(4*a*) *Activity of γ G antibody.* Table 1 shows that after destruction of the γ M antibody by mercaptoethanol, the remaining opsonic activity of the serum is still effective at 1/50,000 dilution. The 0·1 M fraction above containing 205 μg γ G was active at 1/40,000 final dilution.

Table 1

	Final opsonic titre	Haemagglutinin
Original serum	1/500,000	1/500
Original serum + M.E.	1/50,000	
Purified γ M	1/150,000	
Purified γ G	1/40,000	
Original absorbed with *S. adelaide* or *S. manchui* etc.	1/5,000	1/2
Supernates from quantitative precipitin	1/2,000	1/4

(4*b*) *Activity of γ M antibody.* The original serum was active at 1/500,000 dilution and 90 per cent of this activity was lost after treatment with mercaptoethanol. This clearly inferred that the major part of the original serum activity was due to γ M antibody. To further establish this point, γ M antibody was isolated from antiserum by the following steps. 70 ml. of antiserum (2 × 35 ml.) were passed through 'Sephadex' *G*200 columns (62 × 45 cm) using 0·2 M *tris*-HCl buffers at *p*H 8·0 (ref. 5). The leading peaks were pooled, concentrated and centrifuged for 6 h at 80,000*g* to remove lipoproteins which floated to the top of the tubes and were discarded. The remainder was then dialysed against 0·1 M phosphate buffer *p*H 6·5 and applied to a DEAE-cellulose column (26 × 1·2 cm) previously equilibrated with this buffer. The eluate with 150 ml. of 0·1 M phosphate *p*H 6·5 was discarded and the macroglobulins eluted with 1·0 M phosphate buffer *p*H 6·5. The α_2 macroglobulins were then removed by block electrophoresis on polyvinyl chloride in veronal buffer 0·2 M *p*H 8·5 and the γ M globulins concentrated by pressure dialysis. This material gave a single sedimenting peak with uncorrected sedimentation coefficient of 18*S* on analysis in the Spinco model *E* ultracentrifuge and a single precipitin band on electrophoresis against sheep-anti-rabbit globulin antiserum.

The purified macroglobulin fraction was still active at approximately 1/150,000 dilution when returned to the original volume of antiserum fractionated. Bearing in mind the difficulties of purifying macroglobulins without aggregation or denaturation, these results strongly suggest that the major part of the original serum activity was due to γ M antibody.

(5) *Demonstration that the anti-lipopolysaccharide antibody is the active opsonin by elution from the lipopolysaccharide–antibody complex.* The antibody contained in 10 ml. of the rabbit antiserum was precipitated by the addition of 4 mg of the *S. adelaide* lipopolysaccharide representing the amount of antigen at the equivalence point. The precipitate was washed twice with saline, then dissolved in 2 M sodium chloride + 4·0 M urea in borate buffer *p*H 8·6. After 24 h at 4° C the suspension was centrifuged at 60,000*g* for 1 h and then dialysed overnight with stirring against 1 l. 0·1 M phosphate buffer plus 4 M urea at *p*H 6·5. The suspension was then passed through a DEAE-cellulose column (26 × 1·2 cm) previously equilibrated with the 0·1 M buffer containing urea. The column was eluted with 50 ml. of this buffer followed by 50 ml. of 1 M phosphate + 4 M urea at *p*H 6·5. The eluate in the latter buffer was concentrated to 2 ml. by pressure dialysis to give a final protein concentration of 150 μg per ml. This material agglutinated *S. adelaide* rapidly on a slide test and, when examined for its intraperitoneal opsonic activity, was found to be very active

up to dilutions of 1/40,000—the end-point was not reached in this experiment.

(6) *Confirmation that the antibody precipitable with lipopolysaccharide is the same as that responsible for the intraperitoneal killing.* That the antibody responsible for the intraperitoneal killing was the same as the 035 antibody measured by precipitation with lipopolysaccharide was made more certain by the finding that absorption with *S. manchui* or *S. alachua*, both 035 strains, reduced the opsonic activity to 1 in 5,000. Concurrently, the haemagglutinating titre against *S. adelaide*-sensitized red cells fell from 1 in 500 to 1 in 2 (Table 1).

We have demonstrated that in the rabbit antiserum used there were 66 μg of macroglobulin antibody directed against the 035 antigen of *S. adelaide*. This was effective in promoting intraperitoneal killing of the organism when diluted 1 in 500,000 and, on the assumption that all of this antibody was bound to the 10^6 bacteria injected, a simple calculation can be made of the numbers of antibody molecules per bacterial cell. For the calculations we used 10^6 as the molecular weight of γ M and 6×10^{23} as Avogadro's number. With the data given here this works out at eight molecules of γ M per bacterium. Similar calculations with the γ G data lead to a figure of 2,200 molecules of γ G per bacterium. Since it is rather unlikely that all the available antibody would be bound to bacteria at this high dilution, the actual numbers of bound antibody molecules per cell are probably less than those above.

A further simple calculation, using available data on the dimensions of immunoglobulin molecules, reveals that an organism like *S. adelaide* could accommodate approximately 10,000 γ M molecules in a close-packed monolayer on the surface of one bacterium. It seems, therefore, that the time-honoured idea that opsonization involves a change of surface charge due to coating bacteria with a layer of antibody is inaccurate at the least and probably invalid.

The striking difference in opsonic efficiency between γ G and γ M is reminiscent of the recent finding of a similar difference in haemolytic efficiency[6]. In the haemolytic system complement is involved and the relative efficiencies of the two types of antibody molecule can be explained by postulating that two closely adjacent molecules of γ G are needed to bind complement as a bridging molecule. On the other hand, the large γ M molecule may be able to fix complement in an intramolecular fashion. Could the same explanation apply to the opsonic system? Certainly there is ample evidence that complement, if present, will promote phagocytosis[7,8], but whether its participation is mandatory is uncertain. The most persuasive data are those of Nelson, who showed that erythrophagocytosis needs the formation of $EaC_{1,4,2,3c}$ before it occurs efficiently[9].

In our system the end-point measured was the loss of bacterial viability following phagocytosis. While this does not affect the calculations of the numbers of molecules necessary for the whole process to occur, it could be that complement is mainly involved after phagocytosis, in the intracellular events which led to death of the bacterium. Even allowing for this uncertainty, it seems that new explanations of the mechanisms of opsonization must be sought, encompassing the following points: (*a*) the small numbers of antibody molecules required; (*b*) the biological inertness of antibody itself, unless supplemented by other factors; (*c*) the enzymatic activities of the whole complement system after activation by antigen/antibody complexing. Nelson's suggestion that this opsonic mechanism involves some or all of the components of complement seems increasingly feasible[9].

We thank Miss P. Johnston and Mr. D. Horsfall for excellent technical assistance and the National Health and Medical Research Council of Australia and the U.S. Public Health Service for support of this work by grants.

6571st Aeromedical Research Laboratory, Holloman Air Force Base, New Mexico

THE rapid accumulation of new data concerning individual differences in chimpanzee blood has been reported in a series of articles[1-4]. The relative ease with which group-specific isoantisera have been produced in chimpanzees not only by isoimmunization but also by cross-immunization with human red cells is surprising when compared with the situation in man[5,6]. That a constitutional difference may be the explanation is suggested by the observation that many of the immunized chimpanzees become autosensitized[7,8]. If man were as readily sensitized as chimpanzees, the practice of blood transfusion would be seriously hampered.

At the time we published our previous report[1] as many as nine different standardized antisera were available, which defined more than 500 different blood group combinations in chimpanzees. In the meantime, antisera of additional specificities have been produced. Since for further progress standardized reagents are essential, this has created the need for a panel of chimpanzees of known blood groups to be used as reference standards. The establishment of such a panel became feasible when the large colony of chimpanzees maintained by the U.S. Air Force at the Holloman Air Force Base was made available for medical research purposes, specifically for transplanta-

tion studies. From a total of ninety-seven chimpanzees tested, a permanent panel of twenty-seven animals has been selected for their blood types. Blood samples from this 'Holloman panel' are now available to other research workers, together with our antisera of standard specificities. This should foster the dissemination of information and encourage work elsewhere. At the same time some of the animals from the panel are being used for further immunization experiments. In this article, observations demonstrating the usefulness of the panel will be described.

In one experiment, fifteen chimpanzees from the panel were immunized, some with human blood and others with blood from chimpanzees selected for their blood types. The blood was injected by both the intravenous and intramuscular route, and in a few cases subcutaneously and/or intraperitoneally, in doses of 4–7 c.c. No adjuvant was used. Two weeks after the third injection, which was 3 months after the experiment was started, four of the twelve chimpanzees that were tested already showed the presence of isoantibodies (see Table 1). Of these four, one chimpanzee (Billy) had been immunized with human blood, and the other three with blood from individual chimpanzees.

The tests were undertaken using three different techniques, namely, the saline agglutination, the antiglobulin and the ficinated red cell methods. In addition to the direct tests, titrations were carried out as indicated on the last line of Table 1. As can be seen, the four chimpanzee antisera differed from one another in specificity. They also differed in specificity from all the antisera of our previous immunization experiments. It is of interest to note that when the four animals were re-tested a month later, without any intervening injections, their sera exhibited a change in specificity. As shown in Table 2, there was no longer convincing evidence of antibodies in Mandy's serum, while the sera of the other three chimpanzees now all gave parallel reactions. The experiments are being continued.

The tendency of antisera to change their specificity during the course of an immunization poses a serious problem for the production and maintenance of an adequate supply of standardized antisera. This situation also exists in man, though to a lesser degree, when volunteer donors are used for the production of anti-Rh sera, for example. In some cases it becomes necessary to absorb out interfering antibodies from the antisera. Such a problem recently encountered by us in the chimpanzee could be resolved in that way with the aid of the Holloman panel. We had noticed that the anti-**A**^{c} sera* obtained after the third immunization of the original anti-**A**^{c} donor (Malcolm) appear to be giving a higher percentage of positive reactions than anti-**A**^{c} sera from earlier bleedings. We then re-tested chimpanzees that had previously been found to be **A**^{c} negative, and found that some of them reacted positively with the new antiserum. Moreover, when chimpanzees on the Holloman Panel were tested in parallel against the new and the previous anti-**A**^{c} sera, discrepant results were obtained. It was then clear that the serum from the later bleeding contained antibodies in addition to anti-**A**^{c}.

Marc, 172	v.B	0	0	0	0	0	0

Absorption and titration experiments on this serum, as shown in Table 3, confirmed the presence of another antibody besides anti-**A**^{c}. The serum agglutinated in high titres not only red cells from chimpanzees known to be **A**^{c} positive (Frans and Went) but also some of those known to be **A**^{c} negative (Val and Pix). However, by absorbing the serum with the red cells of Val (**A**^{c} negative) the interfering antibody could be removed with scarcely any effect on the titre of the anti-**A**^{c} antibody. Conversely, absorption with Frans's red cells (**A**^{c} positive) removed the anti-**A**^{c} from the antiserum, leaving behind the newly formed antibody, which we now designate as anti-**I**^{c}. In this way, by suitable absorption of Malcolm's antiserum from recent bleedings, it was possible to produce two specific reagents, namely, anti-**I**^{c} as well as the old anti-**A**^{c}. The specificities of these two reagents were

* To avoid ambiguity, symbols for blood factors and their corresponding antibodies are printed in bold type, and symbols for agglutinogens, phenotypes and blood-group systems are printed in regular type.

* Parentheses indicate weak agglutination with the respective reagent, or that clumping occurred only by the antiglobulin method and not by the saline agglutination method.
† The symbols used here have the following significance: c, cef; E, CEf; F, CeF; EF, CEF, and C, Cef.

established with blood samples from twenty-five chimpanzees of the Holloman Panel (Table 4).

The experiments just described demonstrate the value of the Holloman Panel for the continuation and further development of the immunogenetic studies on chimpanzees.

The experiments also underline the importance of obtaining large samples of sera at each stage of the immunization. For this purpose, plasmapheresis techniques have been adapted for use in chimpanzees and other non-human primates, in collaboration with Mr. J. Davis, Dr. P. Day and Miss Lynn Hiller of the National Institute of Arthritis and Metabolic Diseases. The methods of overcoming the problems of vasoconstriction and coagulation in plasmapheresis of non-human primates will be reported later.

The Holloman Panel is also being used in other immunogenetic investigations. Since the animals have all been under long-term observation, and have been investigated thoroughly to exclude the presence of communicable diseases, their blood is now being used for immunization experiments in man. Furthermore, the Panel is beirg used for investigations of platelet and leucocyte groups by Dr. N. R. Shulman[9], for studies on Gm and Inv serum groups in collaboration with Dr. P. Alepa and Dr. W. Terry[10], and for studies on cross-immune isoprecipitins in collaboration with Dr. E. Lichter of the National Institute of Allergy and Infectious Diseases.

The experiments carried out in the Laboratory of the Office of the Chief Medical Examiner of New York City were supported by U.S. Public Health Service grants. Some of the antisera and blood samples were obtained from Yerkes Regional Primate Research Center, Emory University, Atlanta, Georgia. The work was assisted by Mrs. Eve B. Gordon, Miss Pat Ryan, Mrs. Dina Santana Bracco, and Miss Sybil Gordon. The completion of the investigations was assisted by the use of facilities of the Hofstra University, Long Island, N.Y.

INHIBITION OF RADIATION-INDUCED LEUKAEMIA BY THE INJECTION OF HAEMATOPOIETIC TISSUE: A STUDY OF CHIMAERISM

By MISS VALERIE WALLIS, DR. A. J. S. DAVIES and PROF. P. C. KOLLER
Chester Beatty Research Institute, Institute of Cancer Research: Royal Cancer Hospital, Fulham Road, London, S.W.3

KAPLAN has shown that after four doses of sublethal X-irradiation spaced at weekly intervals *C57BL* mice develop lymphatic leukaemia[1]. It has been demonstrated that the thymus is essential for this leukaemia development[2], but that it need not be present during the irradiation. A mouse thymectomized before irradiation, which is given a syngeneic thymus from a new-born mouse as a subcutaneous graft soon after the final dose of irradiation, can, however, develop leukaemia[3].

For leukaemia development most of the haematopoietic tissue has to be irradiated; the shielding of one femur[4], the sternum[5] or the spleen[6] during irradiation greatly reduces the leukaemia incidence. The injection of syngeneic bone marrow cells soon after irradiation also inhibits the development of leukaemia[7], but allogeneic bone marrow is ineffective[8]. With reference to these results, Koller, Davies and Doak[9] wrote: "It seems likely (on the assumption that induced tumors arise directly from irradiated cells) that the ineffectiveness of allogenic bone marrow in altering the carcinogenic effect of the radiation is due to its failure to persist. Thus, when isogenic marrow, or shielding, was resorted to, the treated animals contained populations of irradiated and non-irradiated cells between which selective competition probably favored the non-irradiated cells and, consequently, fewer tumors arose. Animals treated with allogenic marrow, having eliminated the donor cells because of inadequate suppression of the immune responses, contained only irradiated cell populations and the incidence of tumors was therefore comparable to that in uninjected animals". This is supported by the fact that to get maximum inhibition of leukaemia development by syngeneic bone marrow cells a large number of cells must be injected intravenously soon after the last of the four doses of irradiation[10]. These would also be the conditions most likely to lead to the establishment of cellular chimaerism.

In order to test the hypothesis that leukaemia development is inhibited when the injected cells survive and proliferate in the irradiated host, it is necessary to be able to distinguish between the irradiated host cells and the unirradiated donor cells. By making use of a cytologically marked strain *CBA/T6T6* the two types of cell can be distinguished easily. (*C57BL* × *CBA/T6T6*)F_1 mice which have one small marker chromosome, were used as the irradiated hosts and were injected with *CBA/T6T6*

cells with two $T6$ markers or *BALB/c* cells which are unmarked. (*C57BL* × *CBA/T6T6*)F_1 mice were given four doses of 200 r. at weekly intervals starting when one month old. A 220-kV Westinghouse X-ray machine, half value layer 0·4 mm copper, focal distance 100 cm, dose-rate 60 r./min, was used with no added filtration. Within 1·5 h after the last dose of irradiation, the mice were injected intravenously with either 30×10^6 *CBA/T6T6* bone marrow cells, or 30×10^6 *CBA/T6T6* spleen cells, or 1×10^6 *CBA/T6T6* lymph node cells or 30×10^6 *BALB/c* bone marrow cells. In each case the cells were suspended in 0·4 ml. of medium '199'. Some mice were killed during the latent period between irradiation and the appearance of leukaemia and cytological preparations made, basically by the methods of Ford and Hamerton[11] and Rothfels and Siminovitch[12], to see whether dividing cells in the bone marrow, spleen and thymus were of host or donor origin. The rest of the mice in each group were left to find the leukaemia incidence. Mice were killed as they became recognizably leukaemic (from 112 days after the last irradiation).

To determine whether the leukaemia had arisen from the irradiated host cells or the unirradiated injected cells, either the spleen or thymus of the leukaemic mouse was transplanted into host and tissue-donor strain mice. Chromosome analysis was made of cells from the bone marrow, spleen and thymus of leukaemic mice.

Results

(1) *Leukaemia incidence.* The leukaemia incidence in the different groups of mice is shown in Figs. 1 and 2. Day 350 after the final irradiation was taken as an end-point for the experiments since the leukaemia incidence had nearly reached a plateau in all groups of mice by this time. The incidence was significantly lower in mice injected with *CBA/T6T6* bone marrow ($P < 0{\cdot}001$) or *CBA/T6T6* spleen cells ($P < 0{\cdot}001$) than in control mice. Neither injection of *CBA/T6T6* lymph node cells nor *BALB/c* bone marrow cells lowered the leukaemia incidence. In the mice injected wuth *BALB/c* bone marrow, the latent period between irradiation and the diagnosis of leukaemia was significantly longer than in control mice ($P < 0{\cdot}01$), and, at days 150, 200 and 250 after the final irradiation, there was a significant difference between leukaemia incidence in mice given allogeneic bone marrow and uninjected control mice. The final incidence in the two groups was not, however, significantly different.

(2) *Transplantation.* All leukaemias on being tested for transplantability proved only to grow in F_1 mice, suggesting that the leukaemias had arisen from the irradiated host cells and not from the injected unirradiated cells. Even in the few mice in which the injection of *CBA/T6T6* bone marrow or spleen cells had failed to inhibit leukaemia development, the leukaemias were nevertheless of F_1 type.

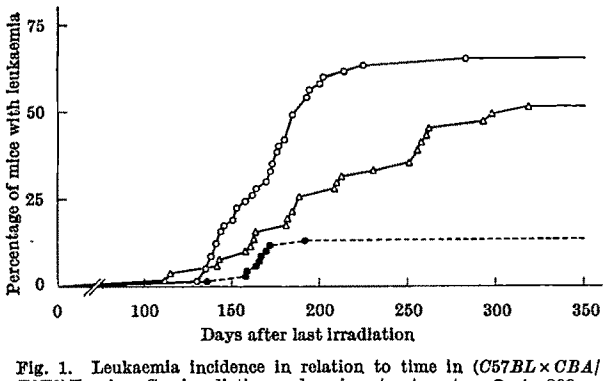

Fig. 1. Leukaemia incidence in relation to time in (*C57BL* × *CBA/T6T6*)F_1 mice after irradiation and various treatments. ○, 4 × 200 r.; △, 4 × 200 r. + *BALB/c* bone marrow cells; ●, 4 × 200 r. + *CBA/T6T6* bone marrow cells

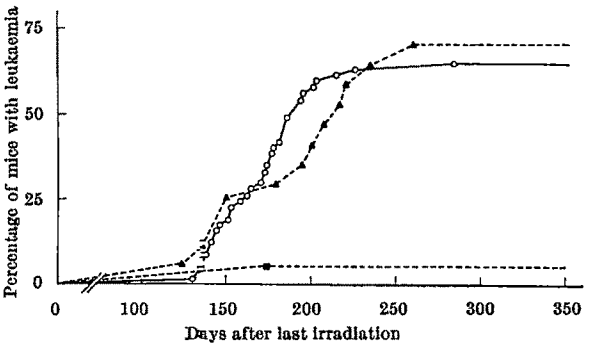

Fig. 2. Leukaemia incidence in relation to time in (*C57BL* × *CBA/T6T6*)F_1 mice after irradiation and various treatments. ○, 4 × 200 r.; ▲, 4 × 200 r. + *CBA/T6T6* lymph node cells; ■, 4 × 200 r. + *CBA/T6T6* spleen cells

(3) *Chromosome analysis of mice during the preleukaemic period.* The chromosome analysis of potentially leukaemic mice during the pre leukaemic period is shown in Table 1. It can be seen that mice injected with *BALB/c* bone marrow cells or *CBA/T6T6* lymph node cells had only host cells dividing, whereas after the injection of *CBA/T6T6* bone marrow or spleen cells, the donor cells predominated. The analysis of thymus and spleen was incomplete, but showed the same proportions of host and donor cells as the bone marrow, except in one mouse indicated in Table I.

Table 1. CHROMOSOME ANALYSIS OF MICE DURING PRE-LEUKAEMIC PERIOD

Treatment	Days after last irradiation	No. of mitotic cells identified in bone marrow	
		Host	Donor
4 × 200 r. + 30 × 10^6 *BALB/c* bone marrow cells	30	87	0
4 × 200 r. + 30 × 10^6 *CBA/T6T6* bone marrow cells*	40	0	119
	70	0	131
	125	1	64
4 × 200 r. + 30 × 10^6 *CBA/T6T6* spleen cells	30	1	66
	98	1	96
4 × 200 r. + 1 × 10^6 *CBA/T6T6* lymph node cells	77	56	0

* In one mouse 3/25 cells scored in the spleen were of host type.

(4) *Chromosome analysis of leukaemic mice.* Table 2 shows the results of chromosome analysis of leukaemic mice. Several of the leukaemias arising in the F_1 mice after injection of *CBA/T6T6* bone marrow, spleen or lymph node cells had appreciable numbers of cells with two $T6$ markers and more than forty chromosomes, although leukaemias transplanted only into F_1 mice. It should be noted that a few cells with two $T6$ markers were found in one leukaemic mouse which had been injected with *BALB/c* bone marrow cells, and that in two F_1 mice, which had been given *CBA/T6T6* cells, some cells with three $T6$ markers were seen.

(5) *Chromosome analysis of mice during post-leukaemic period.* Table 3 gives the results of the chromosome analysis of non-leukaemic mice which were killed more than 350 days after irradiation and injection of *CBA/T6T6* bone marrow or spleen cells. It can be seen that in most mice a large proportion of the dividing cells were of donor type, although there were also appreciable numbers of dividing host cells especially in the spleen. Three of the mice had some abnormal cells present, including a few with three $T6$ markers.

Discussion

(1) *Leukaemia incidence.* The leukaemia incidence after four sub-lethal doses of irradiation in the (*C57BL* × *CBA/T6T6*)F_1 mice used in these experiments was 65 per cent, which is significantly lower than that found in *C57BL* mice in this laboratory (90 per cent) and by Kaplan and Brown (95 per cent) (ref. 1). It is, however, very similar to that found by Ilbery[13] in (*C57BL* × *CBA*)F_1 mice, and by Law and Potter[14] in (*C57BL* × *A*) F_1 mice. Kaplan *et al.*[8], who used another strain combina-

tion (*C57BL* × *BALB/c*)F_1, reported a much higher incidence (92 per cent). Although the overall incidence differed, the mean latent period between irradiation and the appearance of leukaemia was very similar in both parental *C57BL* and F_1 mice, which seems to indicate that the same leukaemia induction mechanism is operating in the F_1 mice as in the parental mice. This is one assumption which will be made in discussing the experiments reported here.

The leukaemia incidence in F_1 mice after the injection of *CBA/T6T6* bone marrow cells (14 per cent) or *BALB/c* bone marrow cells (51 per cent) confirms the results of Kaplan *et al.*[8,10] using *C57BL* mice, which showed that injection of syngeneic bone marrow results in a much decreased incidence, whereas allogeneic bone marrow is ineffective. The present experiments also showed that the injection of parental spleen cells was as effective as injection of parental bone marrow. This observation was, perhaps, foreshadowed by the findings of Lorenz *et al.*[6] that spleen-shielding during irradiation of *C57BL* mice resulted in a very low leukaemia incidence. It should be mentioned that many of the F_1 mice given parental spleen cells developed wasting disease, which can be attributed to a reaction of the injected, immunologically competent spleen cells against the other parental antigens of the F_1 recipient. The wasting disease was fatal in 40 per cent of the mice. This reaction was exaggerated when lymph node cells were injected and necessitated the reduction of cell dose; mice given 10×10^6 lymph node cells all died, while mice which received only 1×10^6 lymph node cells all survived.

In the present experiments the injection of parental lymph node cells was found to be ineffective in reducing leukaemia incidence below control levels. That this is not due solely to the small cell dose which could be injected is shown by unpublished experiments in this laboratory in which the injection of 30×10^6 syngeneic (*C57BL*) lymph node cells into *C57BL* mice failed to reduce leukaemia incidence.

The latent period was found to be not significantly different from that in the irradiated but uninjected F_1 mice, except in the mice which had been injected with allogeneic bone marrow, where there was a significant increase in the induction time. These were the only mice in which a host-versus-graft reaction could in theory occur. It is difficult to predict what the effect of this reaction might be, since the cell populations involved and their interaction *in vivo* are unknown. It is possible, however, that the reaction against the injected foreign (*BALB/c*) cells in some way retards the leukaemogenic process. One explanation of this could be that the (F_1) target cells for leukaemogenesis are involved in the anti-graft activity and that during this immunological reaction they are reduced in number. This could account for the increase in the induction period in these mice, if the time taken for leukaemia to appear depends on the build-up of a certain number of potentially leukaemic cells. It does, however, seem probable that a graft-versus-host reaction, which should have occurred in irradiated F_1 mice injected with parental spleen or lymph node cells, was ineffective in altering the time of onset of leukaemia and therefore did not affect as target cells the pre-leukaemic host cell population.

(2) *Transplantation.* All leukaemias arising in these experiments, including the few in mice injected with

CBA/T6T6 bone marrow or spleen cells, transplanted only into F_1 mice, strongly suggesting that they had arisen from irradiated host cells and not from the unirradiated donor cells. This test is widely accepted as being conclusive evidence that no parental leukaemic cells are present, but in some respects it may be unsatisfactory. F_1 mice will grow both parental and F_1 tumours. Parental mice, however, will reject F_1 cells and it is difficult to predict whether this rejection could affect the growth potentialities of a few (possibly leukaemic) parental cells mixed in with the F_1 cell populations. In the present experiments no artificial mixtures of known parental and F_1 tumours were used to test the validity of this point, and thus the transplantability test, showing as it did only host cell tumours, must be accepted with some, although slight, reserve.

(3) *Chromosome analysis of mice during the pre-leukaemic period.* The cytological analysis of pre-leukaemic mice showed that no abnormal cells were present. This is in contrast to the results reported in a recent paper by Joneja and Stich[17], who showed that 56 per cent of the mitotic cells in the thymus 7 weeks after irradiation were abnormal. However, in the experiments reported here the analysis of the thymus was inadequate. Joneja and Stich also found very few abnormal mitotic cells in the bone marrow.

The cytological analysis revealed that when either parental bone marrow or spleen cells were injected after the final dose of irradiation, chimaeras were obtained. Recently published results by Ilbery[13] indicated that by 60 days after irradiation none of the injected (*C57BL* × *CBA/T6T6*)F_1 cells could be found dividing in his irradiated (*C57BL* × *CBA*/H)F_1 hosts. This is possibly because he injected a far smaller number of bone marrow cells, 4×10^6 as compared with 30×10^6 in the present experiment. He found a leukaemia incidence of 30 per cent in bone marrow injected mice as compared with 15 per cent in similar mice in the present experiments. Despite this finding, the present results seem to indicate that there is a negative correlation between the incidence of leukaemia and the establishment of chimaerism (see Table 4); this bears out the postulate on which these experiments were designed. Unfortunately it is impossible to know whether a mouse analysed during the pre-leukaemic period would have become leukaemic or not, since cytological analysis necessitates killing the mouse. However, 6 per cent or 14 per cent respectively of the mice analysed after the injection of parental spleen or bone marrow cells should have developed leukaemia, but as so few were actually analysed in the pre-leukaemic period there remains the possibility either that animals can be ostensibly chimaeric during the pre-leukaemic period but still develop leukaemia of host-type (as shown by transplantability) or that some non-chimaeric mice were present but were not detected.

Table 4. RELATIONSHIP BETWEEN LEUKAEMIA INCIDENCE AND CHIMAERISM

Treatment	No. of mice	Leukaemia incidence (%)	Chimaerism
Control 4 × 200 r.	57	65	
4 × 200 r. + 1 × 10^6 *CBA/T6T6* lymph node cells	17	71	—
4 × 200 r + 30 × 10^6 *BALB/c* bone marrow cells	51	51	—
4 × 200 r + 30 × 10^6 *CBA/T6T6* bone marrow cells	66	14	+
4 × 200 r. + 30 × 10^6 *CBA/T6T6* spleen cells	18	6	+

(4) *Chromosome analysis of leukaemic mice.* Several analyses of leukaemias induced in *C57BL* mice by the appropriate irradiation which have been published, and unpublished observations in this laboratory show that chromosome abnormalities are a characteristic of these leukaemias. Thus, one might expect that leukaemias arising in mice injected with parental lymph node cells or allogeneic bone marrow, where there was no evidence for chimaerism during the pre-leukaemic period, would show abnormalities and this was the case. However, these abnormalities which relate solely to the leukaemogenic process complicate the present investigation, where it was hoped to identify both host and injected cells, in those groups which had been chimaeras during the pre-leukaemic period. Despite the fact that all leukaemias transplanted as host-type (F_1), there is a possibility that four populations of cells are present, namely normal and abnormal host cells and normal and abnormal donor cells. This supposes that the leukaemogenic agent(s) can induce abnormalities in the donor cells, without necessarily causing them to become leukaemic. Thus in leukaemias arising in mice injected with parental lymph node cells it is difficult to be sure whether the cells with two *T*6 chromosomes were donor cells or altered F_1 cells. However, no donor cells were found in the preleukaemic period, and all leukaemias transplanted as host type. It therefore seems more likely that the *T*6 chromosome tends to undergo non-disjunction in response to leukaemogenic stimuli. This supposition is supported by the finding of one leukaemic mouse in the group injected with allogeneic bone marrow, which had an appreciable number of cells with two *T*6 chromosomes. In these mice no cells of such a phenotype were introduced and therefore they must have derived either from the irradiated singly marked host, or, less likely, from the unmarked donor cell population. Overall there is, in mice injected with parental lymph node cells or allogeneic bone marrow cells, little evidence that the injected cells are involved in or affected by the leukaemogenic process.

It is of interest in this connexion that Kemp and his collaborators[15] and Hammouda *et al.*[16] have recently described cells among human leukaemic cell populations with two *Ph*¹ chromosomes. In a similar manner to that postulated here for the small *T*6 chromosomes, non-disjunction could have led to a duplication of the *Ph*¹ chromosome; such a mechanism for the development of aneuploid cells is perhaps particularly relevant to cells containing abnormally small chromosomes.

In the groups of mice injected with parental bone marrow or spleen cells there were very few leukaemias, but the cytological analysis of these was likely to have been complicated for the reasons detailed above. As before, cells with one and two *T*6 chromosomes were found as significant components of the leukaemic populations analysed. In one mouse a significant population of cells with three *T*6 chromosomes was observed. Despite the indication that donor cells were involved, it seems likely for the reasons already given, and the fact that all leukaemias transplanted only as host-type, that few if any donor cells are likely to have become leukaemic. It seems then that only if complete or nearly complete chimaerism is established is the leukaemia incidence greatly reduced. However, at the time that leukaemic mice were being killed for cytological analysis no comparable sample was taken from mice which were not at the time leukaemic. There is therefore no estimate of the incidence of chimaerism in non-leukaemic mice between 112 and 410 days after irradiation. To some extent this omission is remedied by the analysis of non-leukaemic mice in the post-leukaemic period.

(5) *Chromosome analysis of mice during post-leukaemic period.* The choice of day 350 after the final irradiation as the end of the leukaemic period was arbitrary. 350 days is about 70 days after the main leukaemic period, which is between 120 and 280 days after irradiation. A few leukaemias did, however, arise in most groups more than 350 days after irradiation. Chromosome analysis and transplantation of these showed similar results to those given previously. The results included in the analysis during the post-leukaemic period were in all cases of non-leukaemic mice. A few mice with abnormal chromosomes were found; similar findings are reported by Joneja and Stich[17]. It is possible that these mice were still in a pre-leukaemic condition. Some mice were still complete chimaeras, which shows that once chimaerism is established it can be long-lived. Many mice had appreciable numbers of host cells, but this was independent of the time after

irradiation and injection. This is of more interest to those working with radiation chimaeras, as it suggests that very late reversion can be a common phenomenon. These findings suggest that during the leukaemic period at least a few non-leukaemic mice with appreciable numbers of host cells would have been found. It seems that complete chimaerism is not a prerequisite for the non-leukaemic condition in these groups of mice.

The problem remains whether the inhibition of leukaemia development in mice injected with parental bone marrow or spleen cells is simply a matter of repopulation of the haematopoietic tissues (including the thymus) by the unirradiated donor cells, or whether the bone marrow liberates some humoral factor which is actively anti-leukaemogenic. Berenblum *et al.*[18] have shown that leukaemia development in *C57BL* mice can be inhibited by the injection of multiple doses of large amounts of sheep spleen homogenate, which suggests that there is a non-species-specific substance present in haematopoietic tissues which is capable of inhibiting leukaemia development. Further investigation is required to resolve this problem.

CELL MULTIPLICATION RATES DURING DEVELOPMENT OF THE PRIMITIVE CARDIAC TUBE IN THE CHICK EMBRYO

By DR. NORMAN J. SISSMAN

Department of Pediatrics, Stanford Medical School, Palo Alto, California

THE transformation of the primitive cardiac tube from a straight hollow blood-containing cylindrical structure into one with the form of an S-shaped loop during early embryogenesis of the heart has been described in detail from a morphological point of view[1–5]. There is as yet, however, little understanding of the mechanisms by which the change is effected. During this period of development, increases in the length and diameter of the tube must be accompanied by an increase in the total number of cells in the two layers which form the tube, namely, the myoepicardial layer (outer mantle) and the endocardial layer (inner mantle). Changes in configuration must be the result of rates of cell population expansion which differ at the same time or have different temporal sequences of change in circumscribed portions of the tube, or both. The present investigation was directed towards the elucidation of some of the patterns of cell multiplication during this period of development in the chick embryo heart by the use of autoradiography with tritiated thymidine. The 'radioactive index', as described by Messier and LeBlond[6] (that is, the percentage of cells in a specified tissue which incorporate tritiated thymidine after controlled exposure), was used as an indicator of relative rates of cell multiplication.

Thirteen chick embryos, from developmental stages 10–17, inclusive, as defined by Hamburger and Hamilton[7], were examined. These stages represent ages of approximately 35 h–3 days of incubation; they encompass the period of development from the onset of cardiac contractions in the straight tube to the fullest development of the S-shaped loop. 25 μc. tritiated thymidine, 6·7 c./mmole, contained in 0·1 ml. of normal saline, were injected through a hypodermic needle into the yolk of each embryo immediately below the area vasculosa. Incubation was continued thereafter for 1 h. The embryos were then fixed in 10 per cent neutral formalin, removed from their yolks, and their stages of development determined. Serial sections of the entire heart, 7μ thick, were cut in the transverse plane, and autoradiographs prepared by a slight modification of the dipping method of Messier and LeBlond[8]. Representative portions of both the myoepicardial and endocardial layers of each heart were then selected for determination of their radioactive indices in the following way: seven or eight levels, approximately equally spaced apart from the most caudal to the most cephalic ends of the heart tube, were selected. At each level four adjacent microscopic sections were examined. For the myoepicardial layer, in each of the sections at each level, between two and six identical areas, arbitrarily chosen but approximately equally spaced around the circumference of the layer, were marked off, each area being that portion of the layer enclosed by a microscope eyepiece grid which delineated an area of 1,000μ^2 under a magnification of × 970. The radioactive index was then calculated after counting, with a hand counter, the number of radioactively labelled cells and the total number of labelled and unlabelled cells in each area. Fig. 1 illustrates the method for the myoepicardial layer. The radioactive indices of the endocardial layer, which in all embryos was 1-cell-diameter in thickness, were determined by counting cells around the entire circumference of this layer in each section examined. Totals of between 6,000 and 23,000 cells in each embryo heart were counted.

After preliminary inspection of the data, the primitive heart tube of each embryo was divided anatomically along its cephalocaudad axis into three parts; the primordia of the atrial, ventricular and bulbar chambers. Because it is impossible to separate with certainty the atrial from the ventricular primordia before stage 12, the cardiac tube caudal to the bulbus at stages 10 and 11 was divided into cephalic and caudad halves, and the former classified for analysis as 'ventricle' and the latter as 'atrium'. Analysis was carried out to answer the following questions: (1) Do the mean radioactive indices of each layer of the three chamber primordia increase or decrease significantly with advancing development? (2) Is there a significant difference between the mean radioactive indices of the myoepicardial layer compared with those of the endocardial layer at any or all of the stages of development investigated? (3) Is there a significant difference between the mean radioactive indices of the myoepicardial layer of each of the three chamber primordia compared with each other at any or all of the stages of development? In addition, the radioactive

indices in the local areas of the myoepicardial layer were compared with each other to determine if there was any recognizable pattern to the anatomical distribution of areas with higher or lower indices along any linear axis or around the circumference of the tube.

Statistical analysis of the results consisted of a standard linear regression analysis[9] applied to the radioactive indices as functions of the stages of development. A time scale was sought which would make the radioactive indices increase (or decrease) linearly as a function of age (that is, time). Measurement of the stages of development (ranging from 10 to 17) in the variable log (stage 9) produced reasonably good straight lines. Thus, the regression equation used was:

$$RI = \alpha + \beta \log (S - 9) + e$$

where RI = radioactive index; S = stage; e = observational variability about the regression line; α = intercept of the regression line; β = slope of the regression line.

For each chamber primordium, data for both the myoepicardial and endocardial layers were analysed. Thus, six regression lines were fitted to the data, one for each layer of each chamber primordium. For each line the intercept and the slope were estimated by the method of least squares. These estimates and their standard errors are given in Table 3. The data from which the points were taken are presented in Tables 1 and 2. The best estimate of the radioactive index at any particular stage (S^*) was taken to be the value of the estimated regression line at that stage, that is:

$$a + b \log (S^* - 9)$$

where a = least squares estimate of α; b = least squares estimate of β. By usual techniques, a standard error was attached to this estimated regression value. This standard error involves the variability of the points about the line, the stages entering into the computation of the line, and the stage (S^*). These estimates and their standard errors were used to test for differences between the radioactive indices of the different chamber primordia and the two tissue layers of the tube by means of t-tests. The regression lines were computed using all the observations on all the embryos. Since some embryos had more observations made on them than others, the data were tested for variability due to embryos. None was found for the atrium or ventricle, but there was some evidence of embryo-to-embryo variability for the bulbus. An appropriate weighted regression was computed for the bulbus using the within-embryo and between-embryo variances. The difference between the weighted and unweighted regressions was so small that the latter is the one reported for the sake of consistency with the other two chamber primordia. In the figure in which the regression lines are plotted, the points represent averages for the embryos. Some averages are based on more observations than others, and this has been taken into account. The averages rather than the individual points are plotted to avoid cluttering the graphs with too many points.

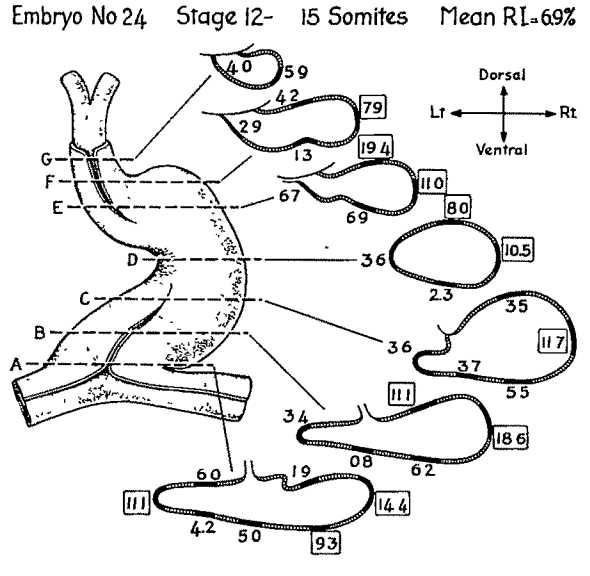

Fig. 1. Diagram of the method of selection of areas for determination of the radioactive index in the myoepicardial layer as exemplified by one of the embryos investigated. On the left is the primitive heart tube at stage 12−, as viewed from its dorsal aspect. The lettered hatched lines show the levels along the cephalo-caudad axis of the tube selected for analysis. Opposite each line is a semi-schematic drawing of the configuration of the myoepicardial layer in cross-section at that level. The blacked-in portions of the layer were those selected, at arbitrary points around the circumference of the layer, for counting. The figures opposite each blacked-in area are the radioactive indices (as percentages) for that area. The figures enclosed in line boxes are those which exceed the mean radioactive index for the entire heart tube

Table 1. RADIOACTIVE INDICES OF THE MYOEPICARDIAL LAYER OF EACH CHAMBER PRIMORDIUM

Embryo No.	Stage	Atrium mean N	Atrium mean R.I. (%)	Atrium mean S.E. (%)	Ventricle mean N	Ventricle mean R.I. (%)	Ventricle mean S.E. (%)	Bulbus mean N	Bulbus mean R.I. (%)	Bulbus mean S.E. (%)

49	17	3	15·0	6·3	4	17·8	5·8	3	13·9	1·0

N is the number of determinations, each determination being the mean value of counts made around the entire circumference of the endocardial layer from four adjacent histological sections.

Table 3. DATA FROM WHICH THE REGRESSION LINES IN FIG. 1 WERE DRAWN AND THE SIGNIFICANCE OF THE SLOPES OF THESE LINES FOR THE MYOEPICARDIAL AND ENDOCARDIAL LAYERS OF EACH CHAMBER PRIMORDIUM

Tissue	Intercept	S.E.	Slope	S.E.	Scale	P-value of slope
Atrial myoepicardium	1·6	0·7	9·1	1·0	$\times 10^{-2}$	1%
Ventricular myoepicardium	0·7	0·7	11·0	1·0	$\times 10^{-2}$	1%
Bulbar myoepicardium	0·3	0·6	5·4	0·8	$\times 10^{-2}$	1%
Atrial endocardium	24 5	2·5	−5·7	3·8	$\times 10^{-2}$	10%
Ventricular endocardium	21·6	2·4	−2·4	3·5	$\times 10^{-2}$	N.S.
Bulbar endocardium	33·1	3·0	−20 0	4 5	$\times 10^{-2}$	1%

Fig. 2 shows the regression lines calculated to determine how the mean radioactive indices of the layers of each chamber change with advancing development, and Table 3 presents the data from which these lines were plotted. These show that there is a significant progressive increase in the mean radioactive indices of the myoepicardial layer in each of the chamber primordia with advancing development. There is no significant change in relation to age in the indices of the endocardial layer of the atrial or ventricular primordia, but the mean radioactive index

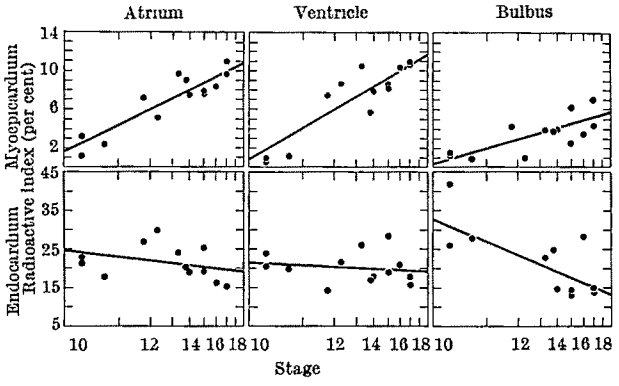

Fig. 2. Regression lines for the endocardial and myoepicardial layers of each chamber primordia plotted against stage of development. The stages of development are represented along the abscissa of the graphs on a semi-logarithmic scale. The data from which the points on the graphs are derived are recorded in Tables 1 and 2 and the values from which the regression lines were derived are in Table 3

of the bulbar endocardial layer decreases to a significant degree with advancing age.

Table 4 compares the mean radioactive indices of the endocardial layer with those of the myoepicardial layer at stages 10 and 17. In each of the chamber primordia at these two stages of development, the mean index of the endocardium is higher than that of the myoepicardium to a significant degree. Since the values for the myoepicardial layer increase with advancing development and those of the endocardium either do not change or decrease with age, the fact that there is equal significance to the difference between the two layers at the earliest and latest stages investigated indicates that the endocardial layer throughout the length of the tube has a significantly higher radioactive index during the entire period of development studied.

Table 4. COMPARISON OF THE RADIOACTIVE INDICES OF THE MYOEPICARDIAL AND ENDOCARDIAL LAYERS OF EACH CHAMBER PRIMORDIUM AT STAGE 10 AND STAGE 17

Stage	Tissue	Myoepicardial mean R.I.	*S.E.*	Endocardial mean R.I.	*S.E.*	*P*-value (difference)
10	Atrium	1·6	0 7	24 5	2·5	1%
	Ventricle	0 7	0 7	21 6	2 4	1%
	Bulbus	0 3	0·6	33·1	3·0	1%
17	Atrium	9·9	0·4	19·4	1·5	1%
	Ventricle	10·7	0 3	19·4	1 3	1%
	Bulbus	5 1	0 3	15 0	2 0	1%

Values are derived from the regression lines illustrated in Fig 1.

Table 5. COMPARISON OF THE RADIOACTIVE INDICES OF THE MYOEPICARDIAL LAYER OF EACH CHAMBER PRIMORDIUM AT STAGES 10 TO 17

Stage	Atrium	*S.E.*	Ventricle	*S E.*	Bulbus	*S.E.*	*P*-value of difference Atrium against bulbus (%)	*P*-value of difference Ventricle against bulbus (%)
10	1·6	0·7	0·7	0 7	0·3	0 6	N.S.	N.S.
11	4·4	0 4	4·1	0·4	1·9	0·4	1	1
12	6·0	0 3	6·0	0·3	2·8	0·3	1	1
13	7·1	0 3	7 4	0·2	3·5	0·2	1	1
14	8·0	0 3	8·5	0·2	4·0	0·2	1	1
15	8·7	0·3	9·3	0·3	4·5	0·2	1	1
16	9·3	0·3	10·1	0·3	4·8	0 3	1	1
17	9 9	0·4	10·7	0 3	5·1	0 3	1	1

Values are derived from the regression lines illustrated in Fig. 1.

Table 5 compares the mean radioactive indices of the myoepicardial layer of the individual chamber primordia with each other at each stage. Initial evaluation of the data showed clearly that there were no significant differences between the mean radioactive indices of this layer in either the atrial or ventricular primordia at any stage, and thus no more detailed analysis was carried out. Statistical evaluation of the differences between the bulbus and the other two chambers shows that the values for the bulbus are lower than those for the atrium and ventricle to a significant degree at all stages after stage 10.

No pattern of anatomical distribution of localized areas with higher or lower radioactive indices along any linear axis or around the circumference of the tube could be defined at any stage.

Messier and LeBlond[6] have demonstrated the validity of using the radioactive index determined with tritiated thymidine as an indicator of the rate of cell multiplication in expanding or renewing cell populations. The time of exposure of the tissue to the tritiated thymidine used in this study (1 h) was chosen arbitrarily. An older investigation of growth of embryonic tissues[10] concluded that the duration of the mitotic cycle in early stages of cardiac development in the chick probably is shorter than 1 h; thus, no conclusion can be reached as to whether the differences we have observed in the radioactive indices in different portions of the primitive cardiac tube are the result of variable percentages of cells being in the *S* phase of the cell division cycle at any one time, or whether they result from varying durations of the division cycle which allow more than one division during the hour of exposure, or both. There was not a sufficiently significant enough difference in the grain density of the label of the cells to use this criterion as a means of identifying different generations after incorporation of the label. Further investigations, using serial determinations of the radioactive indices at multiple short intervals of time after the injection of the tritiated thymidine, are necessary to define the duration of the *S* phase of cell division in these tissues. In any case, it is valid to accept differences in radioactive indices as indications of differing rates at which cell populations are increasing, whatever the mechanisms of the differences may be.

No studies similar to these on the primitive cardiac tube have been reported previously. Grohmann[11] has reviewed studies prior to 1961 on the mitotic index of various tissues in the chick embryo and used this method in evaluating the growth of the chick heart during embryonic and foetal development. He found an increase in the mitotic index of the ventricular myocardium from day 1·5 of incubation to day 4, after which the index fell gradually until hatching. This finding correlates with the increase in the mean radioactive index of the myoepicardial layer of the ventricular primordium found in this study, although our observations were made only until the third day of incubation. Grohmann also found considerable differences in the mitotic index in various portions of the heart. At day 1·5 of age the atrial and ventricular myocardial walls had similar mitotic indices; thereafter, until the thirteenth day, the ventricular indices were higher. The endocardial mitotic index exceeded that of the myocardium only on the second day, and then by less than 1 per cent. Differences in the technique of investigation, and the fact that Grohmann examined only three stages of development during the first 3 days of incubation without indicating the stages of development of his specimens in more detail by standards such as those of Hamburger and Hamilton, make his results non-comparable with those of this study.

The increase in the mean radioactive index of the myoepicardial layer of the entire tube during the period studied strongly suggests that there is a progressive increase in the growth increment of this structure. No data from serial determinations of heart size or weight are available to substantiate this interpretation. The reason for the lack of a similar increase in the indices of the endocardial layer with advancing development (and, in fact, the decrease of the values in the bulbar portion of the endocardium) is not apparent. An increase in the thickness of the myoepicardial wall may account for some of the rise in the index of the layer (especially compared with that of the endocardium which remains 1-cell-diameter in thickness), but this appears unlikely to be a major factor. The similarity between the radioactive indices of the atrial and ventricular primordia at all stages of development indicates that these two portions of the myoepicardial layer are growing at approximately equal rates; the bulbus is increasing its cell population

at a slower rate. Rough estimates of relative changes in the size of the chamber primordia, based on Patten's[12] drawings of the developing chick embryo heart, suggest that these correlate with ratio of the indices at various stages of development, but no firm conclusion regarding this can be reached because of doubt concerning the uniformity of the scale of the drawings. Because no significant patterns of growth in localized portions of the myoepicardial tube were found, this investigation is of no value in explaining how differential growth rates result in changes in configuration of the tube.

The high radioactive indices of the endocardial layer at all stages of development were an unexpected finding. One possible explanation is that cells of the endocardial layer are being lost continually from the layer either by sloughing into the adjacent blood stream or by migration through subendocardial tissue, or both; and that, therefore, there must be increased cell proliferation to replace the lost population as well as to increase with growth the total cell population of the layer. The role of direct haemodynamic pressure of the blood circulating through the tube on the cell multiplication rate of the endocardial layer is a specific factor which should be evaluated.

Other factors are probably of importance in any interpretation of both the positive and negative findings of this study and must be the subject of further investigation. Changes in multiplication rates in localized areas which occur more rapidly than at an interval of 1 h (the time of exposure to tritiated thymidine used in this investigation) could not be detected by this method and may be responsible for changes in configuration of the tube. Migration of cells through the myoepicardial and endocardial layers could not be traced. The presence or absence of multinucleated myocardial cells could not be evaluated, and a significant number of these would change the meaning of the radioactive indices. More complete understanding of the mechanisms which influence the morphological changes occurring during this period of development undoubtedly will require experimental interference with the normal sequences of these changes together with more detailed analysis of the cytodynamics of the cardiac tissue.

This investigation of cell multiplication rates of the primitive cardiac tube of the chick embryo from stages 10 to 17 of Hamburger and Hamilton, using the determination of the radioactive indices of various portions of the tube after the administration of tritiated thymidine, shows a progressive increase, with advancing development, in the growth increment of the myoepicardial layer, a lesser rate of cell proliferation in the bulbar primordium compared with that of the atrium and ventricle at all stages of development except the earliest, and a higher rate of cell multiplication in the endocardial layer compared with that of the myoepicardial layer at all stages of development studied. These cell population cytodynamic patterns form a basis on which further investigation of factors influencing the morphological development of the heart can be carried out.

I thank Rupert G. Miller for assistance with the statistical analysis of the material. This work was supported by a grant from the U.S. Public Health Service and partially by a grant-in-aid from the John A. Hartford Foundation.

NEUROLOGICAL DEGENERATION AND REDUCED SERUM VITAMIN B_{12}-LEVELS IN CAPTIVE MONKEYS

By DR. C. E. OXNARD and DR. W. THOMAS SMITH
Departments of Anatomy and Pathology, University of Birmingham

THE recent observation that many primates maintained in captivity on vegetarian diets quickly develop low levels of vitamin B_{12} in their serum[1–3] has led to further investigations to determine whether corroborative evidence of vitamin B_{12}-deficiency can be found. Thus the treatment of nine infant rhesus monkeys with the vitamin markedly increased their growth rates as compared with those of infants reared on non-supplemented vegetarian diets[4]. Atrophy of the mucous membranes of the tongue and cheek was found in nineteen monkeys with low serum levels and within a few weeks most of these lesions disappeared following injections of cyanocobalamin[5]. Preliminary evidence suggested that the low serum levels in rhesus monkeys might be related to their poor breeding performance, though so far it has not proved possible to improve fertility with cyanocobalamin alone[2,6].

The possibility that lesions of the nervous system might result from vitamin B_{12}-deficiency is also relevant as it is known that 'cage paralysis' occurs in captive monkeys and apes[7–10]. Certain resemblances to 'sub-acute combined degeneration' of the spinal cord in man—and in retrospect with vitamin B_{12}-deficiency—have been considered[11–13], although the conclusions were uncertain particularly because macrocytic anaemia was not demonstrated. In a review of degenerative demyelinating diseases in primates, Ruch[14] suggested that vitamin B_{12} may be implicated. It is known that demyelinating lesions in the nervous system occur in a number of other animal species (for example, chick, rat, calf) in vitamin B_{12}-deficiency states[15].

With these facts in mind a neurological study of three groups together comprising fifteen monkeys (*Macaca mulatta*) was undertaken.

Paralysed group (5 *monkeys*). These showed low serum vitamin B_{12}-levels and overt paralysis. Duration of captivity varied from 1·5 to 26 years. Neurological examination presented considerable difficulties. As well as the absence of subjective information and of signs elicited by commands, the recording of objective phenomena was problematical and interpreted cautiously. It is likely that only gross signs were recognized.

Paralysis usually followed a consistent pattern. The worst case presented as a flaccid paralysis of the hind limbs and tail. In the less-affected animals mobility was impaired so that either they did not climb, or they climbed clumsily and with difficulty, bearing the body-

weight mainly on the heels. Clumsiness in moving, though partly due to the weak grasp of the feet, seemed to be less evident if the animals watched their limbs. Sometimes there was intention tremor of the limbs. On examination, trophic changes on the heels and toes and loss of hair and skin on the tail were found. Though such lesions appeared to be painless, hyperaesthesia seemed to be caused in some animals by stroking or rubbing the digits or sole, and by pressure on the muscles and tendons of the leg. It proved almost impossible to test power or tone except in the most paralysed cases. Considerable flexion deformity was obvious in most of the affected animals. Knee, ankle and plantar reflexes, all easily obtainable in animals recently arrived in captivity, were usually absent. Sometimes reflexes in the arms could be obtained, but more frequently these were also absent.

Two animals showed severe, active sudanophilic, spongiform demyelination in the posterior and to a lesser extent the lateral columns of the spinal cord (Fig. 1) associated with axonal degeneration but not with significant gliosis: in one of these two cases there was active demyelination of anterior and posterior nerve roots and the anterior horns showed focal lymphocytic and microglial infiltration and neuronophagia. In the other three cases there was similar but less severe posterior and lateral column demyelination without significant axonal changes. Longitudinal sections showed that in all cases lesions in the white matter were more patchy than was apparent in transverse sections. In all five cases there was variable chromatolysis but no significant loss of the large anterior horn motor neurones.

One of the cases with less severe spinal degeneration also showed extensive, blotchy, more or less symmetrical, spongiform degeneration of the central white matter of the cerebral hemispheres (Fig. 2) accompanied by astrocytic hyperplasia and perivascular cuffing with lymphocytes, lipophages and eosinophil polymorphs. The only other animal with cerebral lesions had been captive for the longest period—26 years: throughout the cerebral cortex there was focal spongiform degeneration and gliosis, diffuse (sometimes laminar) neuronal loss, and atrophy of many residual neurones. Though there was no relevant vascular disease, these cortical changes were difficult to evaluate as the animal had been mildly diabetic for 4 years (on 20 units of insulin daily) and on one occasion 6 months before death was found in hypoglycaemic coma, which might have been a causative factor. It should be stressed that the spinal cord and peripheral nerve lesions in this animal were unlikely to have resulted from the diabetes as they were identical to the changes found in all other affected but non-diabetic animals.

Three cases showed severe, patchy, active sudanophilic demyelination of the peripheral nerves (Fig. 3), related proliferation of Schwann cells and mild lymphocytic and

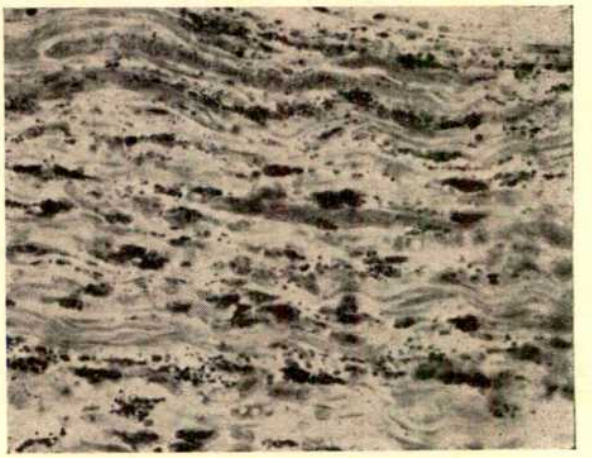

Fig. 3. Severe demyelination of a lateral popliteal nerve. Infiltration with sudanophilic lipophages. (Longitudinal frozen section.) Sudan 3 and 4-haematoxylin. (× 250)

lipophage infiltration; a fourth case showed similar but less-pronounced changes. Degeneration appeared to be most pronounced in the distal parts of the nerves. The peripheral nerves were not examined in the fifth case.

The optic nerves and tracts showed patchy demyelination in the single case in which they were examined.

Long-stay normal group (7 *monkeys*). These showed low serum vitamin B_{12}-levels but no paralysis. Duration of captivity varied from 3·5 to 16·5 years. There were neither trophic lesions on the extremities nor evidence of paralysis. Tendon reflexes in the legs and the plantar responses were usually absent.

Four animals showed mild but definite spongiform degeneration of the posterior and lateral columns of the spinal cord and patchy demyelination of the peripheral nerves, qualitatively similar to the lesions in the paralysed animals. Cerebral involvement was not found.

Short-stay normal group (3 *monkeys*). These showed reduced (and presumably still falling) serum vitamin B_{12}-levels but no paralysis. Duration of captivity was less than 2 years. The animals usually appeared normal with brisk reflexes and definite, repeatable plantar responses.

Two of these showed mild but unequivocal lesions of the spinal cord (Fig. 4) and peripheral nerves similar to those found in the previous 'long-stay normal group'. The brains were not affected.

General haematological findings. The serum vitamin B_{12}-levels were similar to those already reported by Oxnard[2]. Thus, in all the twelve 'long-stay' animals, the range was < 20–80 pg/ml. of serum (compare mean value

35, range <20–70 pg/ml. of serum in 34 'long-stay' animals found previously). The range in the 'short-stay' animals was 60–160 pg/ml., being between the limits previously found in 43 'recently captive' animals (mean value 233, range 110–680 pg/ml.) and those in animals captive for longer than 2 years. The 'short-stay' findings were complicated by the fact that the estimations were made in pregnancy which is known to be associated with reduced levels.

Anaemia was never found. Apart from 'very occasional larger red cells' in one paralysed animal, blood films and absolute values showed no evidence of macrocytosis. In the colony as a whole the routine haematological examination of ninety-one recently captive and seventy-six long-stay monkeys did not reveal anaemia or macrocytosis.

Folic acid assays and marrow smears have not yet been studied.

These preliminary findings indicate that captive monkeys with 'cage paralysis' showed reduced serum vitamin B_{12}-levels associated with spongiform degeneration of the spinal cord, patchy demyelination of peripheral nerves and occasional degeneration of cerebral white matter similar to the neurological lesions of human vitamin B_{12}-deficiency. There are minor differences: in the monkeys, the cord changes were less patchy and sometimes associated with degeneration of nerve roots and anterior horn motor neurones and with more pronounced reactive cellular infiltration.

Similar, but less severe, changes in the spinal cord and peripheral nerves were found in four out of seven clinically normal monkeys which had been captive for periods varying from 3·5 to 16·5 years; also in two out of three clinically normal animals captive for less than 2 years. The fall in serum vitamin B_{12}-level starts early in captivity[2] and therefore accompanies these sub-clinical lesions, which in one case were detected after only 8 months' captivity. It appears that such lesions eventually progress and result in overt paralysis, which affected one animal after only 14 months' captivity.

A cause-and-effect relationship between the reduced serum vitamin B_{12} and the neurological degeneration has not been established, although the similarity to human 'sub-acute combined degeneration' and to the degenerative demyelination in other species[15], together with the considerable objective improvement (at the time of writing) of four paralysed monkeys treated with parenteral cyanocobalamin, are very suggestive. The possibility that other nutritional elements are also deficient cannot be disregarded and it is noteworthy that similar pathological changes have been found in malnourished prisoners of war showing neuropathy[16], and in patients with neuropathy and adult coeliac disease[17,18]. Clinical evidence of chronic gastrointestinal disturbance was not observed in the monkeys. Furthermore, the absence of macrocytosis or other consistent haematological changes suggests that in this species erythrocytopoiesis is relatively resistant to vitamin B_{12}-deficiency.

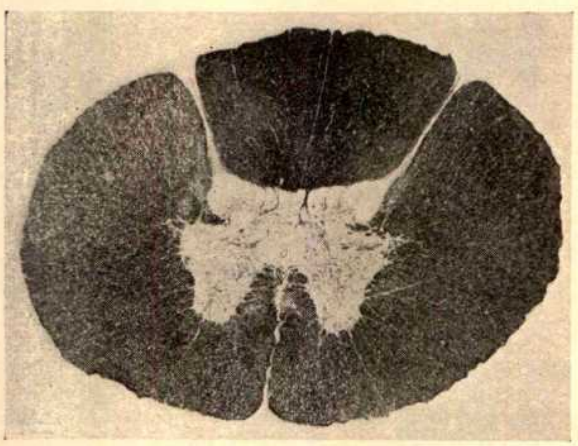

Fig. 4. Asymmetrical spongiform degeneration maximal in one lateral column of the spinal cord. Luxol fast blue-cresyl fast violet. (× *c.* 17)

It seems likely that dietary alterations consequent on captivity, rather than a decrease in absorption or an increase in requirements, account for the fall in serum vitamin B_{12}. Under natural conditions a limited intake of animal foodstuffs (such as insects or other small animals) or coprophagy could provide the small amount of vitamin B_{12} known to be necessary. The animals in the Birmingham colony now receive routine parenteral cyanocobalamin, but it is too early to assess its prophylactic effect either on long-stay or recently introduced inmates. Because of the relative infertility of captive primates with low serum levels[2] it is not yet known if this problem also applies to monkeys born in captivity or if myelination is defective in such circumstances, as has been shown in the chick, calf and rat[15].

Further pathological investigations are being undertaken on the foregoing fifteen and more recently killed animals. In particular, the possibility of faulty absorption of vitamin B_{12} is being considered. There was no evidence of parasitic infestation or of changes suggesting a primary bacterial or viral infection in any animal. The cellular infiltration occasionally noted appeared to be a secondary reaction to neural degeneration rather than the result of a primary infection. A single paralysed animal found to have gross cerebral cysticercosis at necropsy was not included in the series.

Samples of voluntary muscle were always examined but did not show noteworthy changes on routine histological examination, though specialized techniques for intramuscular nerves and nerve endings were not used. Such techniques will be necessary in future investigations, particularly as it appears possible that the peripheral nerves are affected by a distal atrophy or 'dying back'; this type of neural degeneration has aroused considerable interest in recent years[19,20].

Until the relationship of vitamin B_{12} (and other dietetic factors) to the neurological lesions is more precisely defined, the suitability of 'untreated' captive primates for certain types of neurobiological research is suspect. In particular, the association of mental symptoms with human vitamin B_{12}-deficiency sometimes without other neurological disturbance[21] must suggest caution in the use of such monkeys for behavioural and psychological studies. Meanwhile, there is much to be learnt from this experimental model of central and peripheral myelin degeneration.

This investigation has been supported in part by a grant to Sir Solly Zuckerman from the Agricultural Research Council of Great Britain.

ASTROPHYSICS

Mass Ejection by Highly Evolved Stars

THE problem of the surprisingly high abundance of galactic helium which has been observed[1,2] was the stimulus for this work. This communication proposes a new mechanism for rapid mass ejection from highly evolved stars. The mechanism is effective only over a specific, relatively short period of time in the life of the star. The general problem of mass loss from stars is the subject of an excellent review by Weymann[3].

As Schwarzschild[4] shows (see his Fig. 28.3), the red giant phase of stellar evolution is characterized by a convective hydrogen envelope of very low density and a high-density helium core. Between these, in a very narrow transition zone, is the hydrogen-burning shell.

Let us examine closely the state of the star when the hydrogen-burning shell is far out and becoming quite thin. It is our basic contention that because of the high power of dependence of nuclear energy production on temperature, T (as T^{ν}, where $\nu = 13$–20 for the carbon cycle and $\nu = 3{\cdot}5$–6 for p-p burning), the shell will 'suddenly' stop burning. By 'suddenly' I mean in a shorter time than the Kelvin gravitational contraction-readjustment time, τ.

Iben[5] comments on the high sensitivity of the shell energy production rate to small changes in structure. One useful criterion might be when the linear dimension of significant fluctuations becomes comparable with the thickness of the shell.

The second basic contention is that, with the shell energy source stopped suddenly, the envelope will cool rapidly compared with τ. This is guaranteed by the fact that as the stellar envelope expands, highly efficient convective-energy transport supersedes radiative transport in more and more of the envelope. This fact can be appreciated from the calculations by Iben[5], Kippenhahn[6], Hayashi[7] and others.

Now, with the shell source having ended and the envelope relatively cool, the star must readjust gravitationally. The enormous, extended light hydrogen envelope is accelerated radially, that is, falls under gravity, into a heavy helium gas core across a relatively sharp boundary. This process is the classic Rayleigh-Taylor instability.

Whereas in the linear region, short wave-length perturbations grow fastest, in the non-linear range (perturbation amplitudes comparable with or larger than the wave-length, λ) the result is fundamentally different.

The first serious attack on the non-linear Taylor instability problem was made in a pioneering computer calculation ('Macbeth')[8] in 1952 by Pennington, Greyber, Wheeler *et al.*, whose results are not widely known. It is shown that the long wave-length perturbations eventually dominate in the non-linear range. Large spikes of heavy fluid penetrate deep into the light fluid region and bubbles of light fluid extend a small distance into the heavy fluid region. (It can be shown that the results carry over to problems of plasma-magnetic field interface instabilities. In 1957 I suggested a different application of the same process to astrophysics[9].)

Thus we conclude that shortly after the shell has stopped burning, large spikes of helium will surge out from the edge of the core, pushing hydrogen before it. Stellar rotation will merely modify the result. If small amounts of heavy elements or a strong magnetic field were to exist in the outer part of the dense core, they would also be brought to the surface of the star.

From a remarkable paper by Enrico Fermi and John von Neumann[10] we can obtain the result that in the late stages of the instability the heavy fluid should penetrate the light fluid with an acceleration

$$g\,\frac{\rho_1 - \rho_2}{\rho_1}$$

where ρ_1 is the density of the heavy fluid and ρ_2 is the density of the light fluid.

The fact that in our case ρ_2 is negligible compared with ρ_1, so that the acceleration of the spike is about g (the value of the acceleration of gravity at the shell), shows that very considerable mass loss can occur during the Kelvin contraction-readjustment time. Obviously it is to be expected that the Helmholtz instability would occur along the sides of the large spike because of the large velocity difference across the interface, and thus contribute to mixing, eventually breaking up the spike of heavy fluid.

Let us survey briefly some astronomical problems to which the proposed mechanism may be relevant:

(1) Clearly a similar ejection of helium, carbon and heavier elements would be caused by the very sudden end of a helium burning shell (energy production goes as T^{30}). This is relevant to the cosmic element abundance problem.

(2) It is interesting to note that a recycling calculation[2] over the age of the galaxy gave too little helium by a factor of 2—assuming that only at the final supernova phase was matter fed back into the interstellar medium. With the many generations of massive stars between the time of formation of the galaxy and the present, even a slightly earlier ejection of helium into the interstellar medium increases the predicted amount of helium significantly. This seems to explain the helium abundance paradox.

(3) Fowler, Burbidge, Burbidge and Hoyle[11], from a careful attempt to account for the chemical compositions of the peculiar A stars, deduce that a powerful mixing process has been at work so that the products of the interior nuclear synthesis have been brought to the surface. The mechanism outlined here appears to be the mixing process required for the A_p and A_m stars. Conceivably the symbiotic stars such as BF Cyg are in this phase now.

(4) The mechanism may explain the evolution of certain special types of stars which require very substantial mass loss of hydrogen reasonably to account for their chemical compositions. Examples are helium stars[12] such as HD 160641 and carbon stars such as R Cor Bor.

(5) The origin of planetary nebulae[13] and shell stars such as Zeta Tauri may be connected with the mechanism, by the formation of a gas shell from the ejected material.

(6) Conceivably a light element (deuterium, lithium, beryllium and boron) burning shell may form in a star contracting to the main sequence. The ejection of gas caused by the sudden end of such a shell could explain the nebulosity seen around many of these stars by Herbig.

(7) Kopal[14] remarks that many investigations are converging, on several grounds, to the conclusion that pulsations are limited to the outer layers of a star. I would propose that, in some stars, the mechanism triggers the stellar pulsations observed.

(8) If the Hoyle–Fowler massive objects can continue nuclear evolution (despite the relativistic instabilities calculated), perhaps by rotation, until shell burning proceeds to termination, the mechanism might explain

the luminosity variations[15] observed in quasi-stellar radio sources.

It is perhaps worth noting the obvious fact that the process discussed herein cannot show up in the present-day computing machine calculations[5–7] because all quantities are only radial-dependent in such calculations (spherical symmetry).

The mechanism suggests that mass loss should be greater for shells that end earlier (due to higher temperature dependence). Hence the CN cycle stars should have greater mass loss than stars on the *p-p* cycle. Whether the astronomical evidence supports such a prediction is not as yet known.

This work was supported by a grant from the National Aeronautics and Space Administration. I thank the Observatoire de Paris, Meudon, and the Department of Mathematics, Imperial College of Science and Technology, for their hospitality.

A Possible Identification of the X-ray Source *Sco X-3*

THE purpose of this communication is to point out the positional coincidence of the X-ray source *Sco X-3* with an extended H II emission region which may be the remnant of a supernova explosion. Originally, a correlation between supernova remnants and X-ray sources had been predicted by theory and has been verified for the Crab Nebula[1] and for Kepler's supernova *SN* 1604 (ref. 1), although the latter identification has become very doubtful[2].

The position of *Sco X-3* is given as:

R.A. (1950)	Decl. (1950)
17h 23m	−44.3°

This position falls just within the upper opening of the U-shaped H II region No. 114 from Rodgers *et al.*[3,4]. This H II region is described by the authors as a faint, ring-like structure of 50 min width and extending over 5·5° × 5.5°.

Although the star density makes it impossible to classify the object in the Hα *Atlas*[4] according to van den Bergh's[5] criteria as belonging to class III, its general appearance fits remarkably well to that of known supernova remnants. Its size is comparable with the nebula around the radio source Vela *X*, to the Cygnus Loop, to *IC* 443, and to *S* 147, and the latter three objects share additionally its more or less ring-like structure.

No radio source has been reported yet in the direction of the H II region No. 114. However, Hayakawa *et al.*[6] have shown that the active time of radio emission of a supernova remnant may be as short as $\sim 10^3$ years, whereas the X-ray activity may last as long as $\sim 4 \times 10^4$ years. The lack of a detected radio source does not, therefore, bear much evidence against the proposed identification.

It may be noteworthy that the Muslim astrologer, Albumazar, observed in about A.D. 827 a reliably recorded supernova[7] in the tail of Scorpio. It became as bright as the Moon at quadrature ($\sim 10^m$) and was observed for 4 months. If this occurrence should be connected with the H II region No. 114, its present size would have to be explained by expansion during the past 1,140 years. If an absolute brightness of -16^m is assumed for the supernova at maximum, this places it at a distance of ~150 parsec; from this follows a very high expansion velocity of 13,000 km/sec. That rather unlikely value cannot be completely ruled out because of the uncertainties involved in our distance estimation and because expansion velocities of at least 7,000 km/sec are observed in supernovae of type II (ref. 8). An observational check could readily be made, because the annual apparent expansion rate of the H II region would have to be 17 sec/year.

I thank Dr. A. R. Sandage and Dr. Maarten Schmidt for their advice.

PHYSICS

Detection of Weak Microwave Modulation of Light

WE have devised a method of detecting very low levels of modulation on a laser beam, with the object of assessing the performance of microwave light modulators. The system may either be used simply to indicate the presence of modulation, or, in conjunction with a Fabry–Perot interferometer, to demonstrate the existence of optical sidebands as discrete frequencies.

Use is made of the well-known fact that, in general, the adjacent sidebands emerge from an optical modulator with a different plane of polarization from that of the carrier wave[1–4]. Thus, if crossed Nicol prisms are placed on either side of the modulator, the carrier will be suppressed and only the sidebands will emerge from the analyser prism. Kaminow[4] has in fact used such an arrangement to detect modulation from a high-power pulsed magnetron by receiving the emergent light on a photomultiplier tube and displaying the resulting output pulses on an oscilloscope.

The present modulator consists of a crystal of potassium dihydrogen phosphate in a rectangular *TE* 011 cavity fed from a 5-W continuous X-band source. The effective length of the crystal is about 1 cm, and a laser beam passing along the optical axis of the crystal is weakly modulated at the microwave frequency. The depth of modulation, estimated from published values of the electro-optic coefficients of potassium dihydrogen phosphate[5], is about 1 per cent, so that the intensity of the sidebands is 10^{-4} times that of the carrier. To display the optical modulation we impose an audio-frequency modulation on the

microwave source and insert a narrow-band amplifier[6], tuned to the audio-frequency, between the photomultiplier and the oscilloscope. The signal-to-noise ratio achieved with this system is of the order of 100 : 1.

Kaminow[7], using a 5-W X-band source and a more efficient modulator, has been able to photograph the splitting of the carrier and its adjacent sidebands, using a Fabry–Perot interferometer with dielectric mirrors designed for optimum performance at 6328 Å. The modulation index in this case was 0·03, so that the sideband intensity was about 10^{-3} times that of the carrier.

It is doubtful whether such a system would record sidebands as weak as those produced in our experiment, the resolution of the etalon being limited by light scattered from the principal set of rings. However, by incorporating a polarizer and analyser as already described, we may enhance the modulation index of the light entering the etalon, and so reduce the scattering problem. With such a system, used in conjunction with the narrow-band detector and a Fabry–Perot etalon with simple aluminized mirrors, the weak sidebands produced by our modulator are easily observed. The signal-to-noise ratio in this case is about 10 : 1, the reduction from the previous figure being due to attenuation of the light by absorption in the mirror surfaces. We would anticipate an improvement in signal-to-noise ratio of at least an order of magnitude if suitable dielectric mirrors were used in the Fabry–Perot etalon; a further improvement could be made by incorporating a lock-in detector of the type used in nuclear magnetic resonance systems.

Nucleation of Thin Films

DURING an investigation into the electrical properties of evaporated thin films prepared under ultra-high vacuum conditions, it was observed that electrical charge on the surface of glass substrates can affect the nucleation density and initial growth structure of thin films of gold.

The substrates (Corning barium alumino silicate glass No. 7059) were cleaned by detergent wash, ultrasonic agitation and vapour de-greasing; after this process a small charge, generally positive, was found on the glass surface. This could be removed by baking the substrate in vacuum, or by condensing a small amount of gold on to the glass. The removal of positive surface charge appears to be a good indication that nucleation has occurred on the substrate. Negative charge disappears more slowly after nuclei have been formed. The vacuum plant used was diode getter-ion and titanium sublimation pumped, and it was observed that surface charge could be induced on the substrate during pump-down. The ion pump gave a positive charge and the titanium pump a negative charge. Both pumps were optically baffled from the evaporation chamber.

The effect of charge on nucleation was examined by polarizing the ends of a 3 in. × 1 in. substrate so that the surface facing the evaporation source had areas of both positive and negative charge. The surface charge on this electret was adjusted during pump-down to 10^{-8} torr so that the two ends were opposite in sign but about equal in magnitude. Gold was evaporated at a slow rate until the positive charge disappeared, which took about 6 sec after the shutter was opened. Evaporation was continued for a further 3 sec before the source shutter was closed, in order to allow further growth of the initial nuclei so that they were large enough to be observed in the electron microscope. Secondary nuclei formed during this evaporation would be so much smaller than the initial nuclei that they would not be observed.

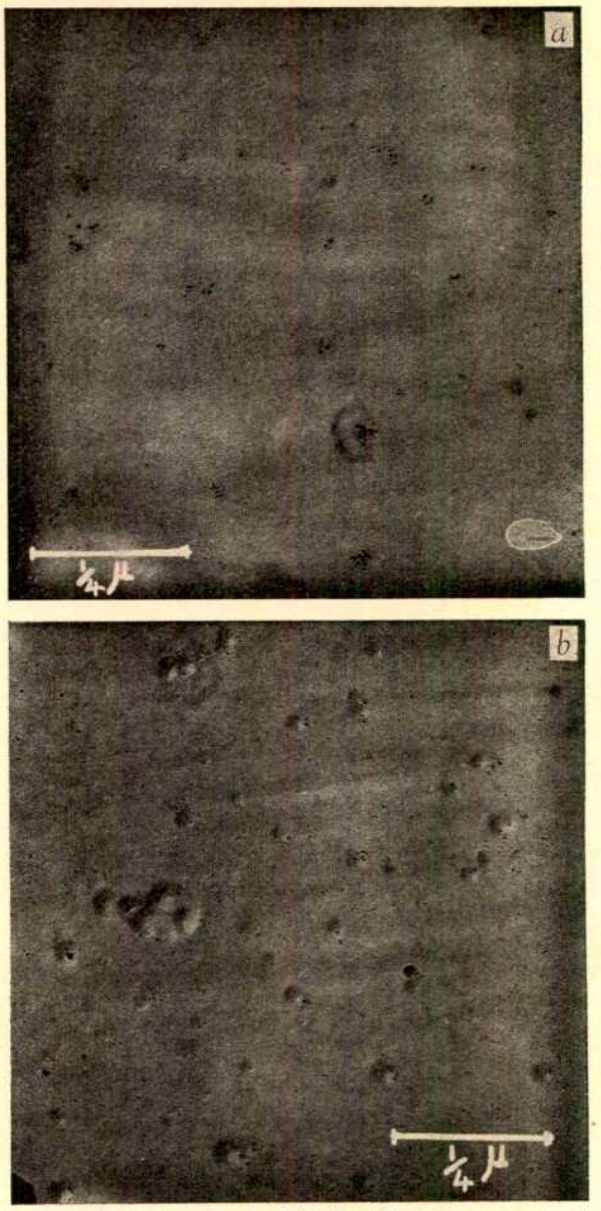

Fig. 1. *a*, Nucleation on a negatively charged surface: charge density $-1{\cdot}1 \times 10^{11}$/cm²; total nuclei density $4{\cdot}4 \times 10^{10}$/cm². *b*, Nucleation on a positively charged surface: charge density $+8 \times 10^{10}$/cm²; total nuclei density $7{\cdot}4 \times 10^{10}$/cm²

The specimens obtained were examined in an electron microscope by transferring the gold film to a thin carbon backing film, and the micrographs are reproduced in Fig. 1. Fig. 1*a* shows the negatively charged substrate, on which the nuclei are dispersed, and appear to be localized around surface imperfections in the glass.

Fig. 1*b* shows the positively charged surface which has a few nuclei present on surface imperfections, and a uniform background of small nuclei. In the positively charged case the total density of nuclei ($7{\cdot}4 \times 10^{10}$/cm²) is close to the charge density (8×10^{10}/cm²) while on the negatively charged surface the density of nuclei is three times less. If in the latter case we consider not the total number of nuclei but the number of cluster sites, the ratio of charge

to sites is 30 : 1. The average particle size of the uniform background in Fig. 1*b* is of the order of 30–40 Å.

The vapour was examined for charge and it was found that under the conditions of evaporation there were some positively charged gold ions, but these represented only 10^{-8} of the total. Free electrons were thermionically emitted from the hot source, but the total density of these during the complete evaporation was at least an order less than the charge density.

It is believed that this behaviour is consistent with nucleation at surface dipoles formed by a positively charged site and a vapour atom, the valence electron from the vapour atom being held by the positive site. On a negatively charged surface the valence electrons are not given up by the vapour atoms and they are not electrostatically bound to the site. The individual atoms will be free to travel some distance over the surface, and if in fact there is a small repulsion between the substrate and the atoms, nucleation will occur only in regions of field divergence on the surface, that is, at surface imperfections.

I thank Mr. J. Cleaver and Mr. J. D. Sinfield for preparing and examining the micrographs.

Transmission Filters for Visible Light

SOLUTION filters have proved to be the most flexible and efficient type of filter. In order, however, to get a sharp cut, a suitable combination of solution filters and/or glass filters is necessary. Such a combination of filters suffers from very low transmission.

We report here the application of some dye solutions as transmission filters for the visible region of the spectrum. Such dye-solution filters have the advantages that (*a*) they have a fairly narrow range of transmission even when used singly, (*b*) the transmission region, as well as the peak, can be easily shifted in the desired direction by adjusting the *p*H of the solution, and (*c*) the maximum transmission of such filters is about 90 per cent on the average. Although a few workers[1–3] have made use of certain dye solutions as transmission filters, we have seen no reports of the shift of the transmission range of such filters with a change in *p*H. We have found that the same dye, at different values of *p*H, can be used in different parts of a filter combination for a sharp cut-off, and suitable mixture of

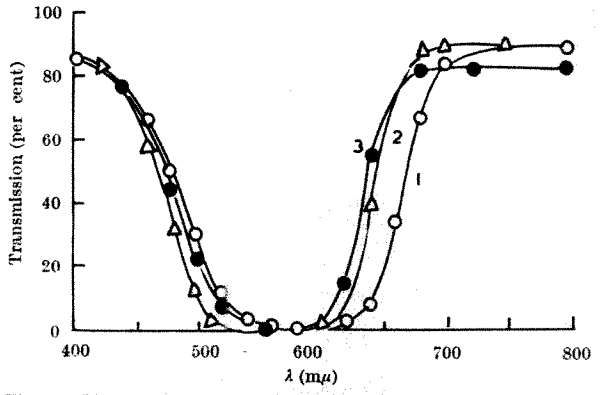

Fig. 1. Plot of percentage transmission against λ for methyl violet (40 mg/l.) in N/100 hydrochloric acid (curve 1), in water (curve 2) and in N/100 sodium carbonate (curve 3)

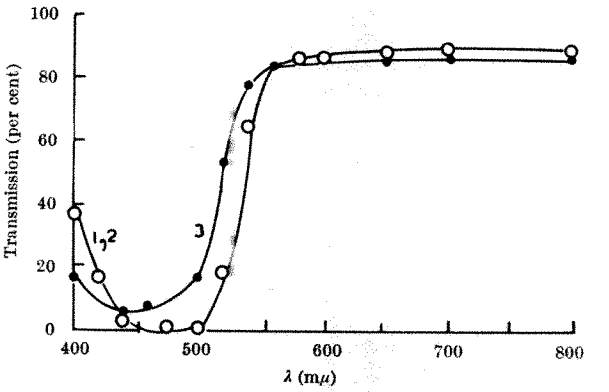

Fig. 2. Plot of percentage transmission against λ for acridine orange (84 mg/l.) in N/100 hydrochloric acid (curves 1, 2), in water (curves 1, 2) and in N/100 sodium carbonate (curve 3)

dye solutions are convenient for transmitting a fairly narrow range of visible light. Table 1 summarizes our observations with some dye solutions at different *p*H values, and plots of percentage transmissions against wavelengths are shown in Figs. 1–5.

The curves of Figs. 1–3 are analogous to those of sharp cut yellow and red glass colour filters (Corning Glass Works)[4]. By suitable combination with infra-red absorbing filters, these can be highly recommended as high-efficiency sharp cut-off filters. That the transmission

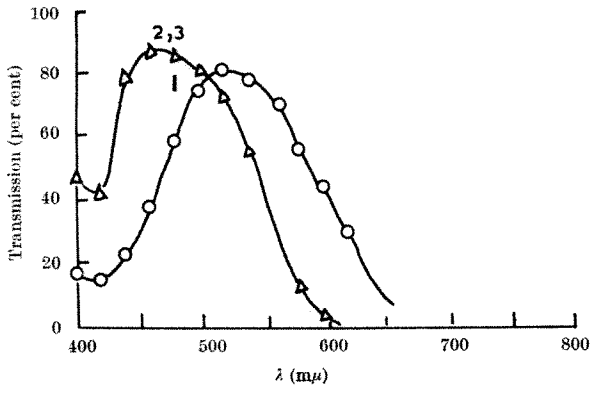

Fig. 4. Plot of percentage transmission against λ for disulphine blue *VN* 150 (80 mg/l.) in N/100 hydrochloric acid (curve 1), in water (curves 2, 3) and in N/100 sodium carbonate (curves 2, 3)

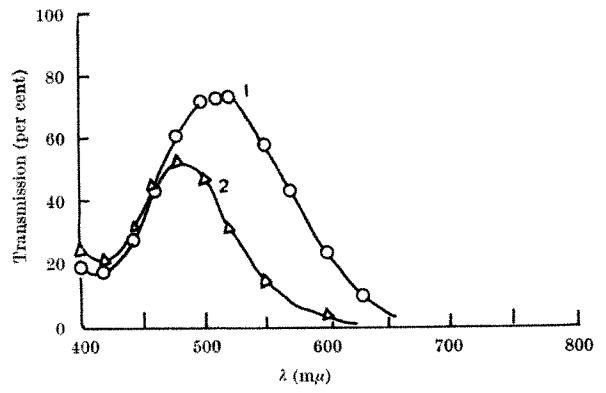

Fig. 5. Plot of percentage transmission against λ for mixed dye system: methyl violet (80 mg/l.) in water and disulphine blue *VN* 150 (80 mg/l.) in N/180 hydrochloric acid. Curve 1 refers to methyl violet/disulphine blue = 1/50 v/v. Curve 2 refers to methyl violet/disulphine blue = 1/5 v/v

region can be altered by changing the *p*H of the solution filters is evident from the curves in Fig. 4. The same effect can also be obtained in a mixed dye system by suitably adjusting the composition of the mixture. The curves obtained with a methyl violet/disulphine blue mixture have been found to bear a close resemblance to those of disulphine blue alone at different *p*H values (Figs. 4 and 5).

These solution filters have been compared with the Hilger and Watts 'Spekker' coloured glass filters. The latter suffer from the limitation that their percentage transmission value is very low (about 14–29 per cent), although the width of the transmission zone is about 60–70 mμ.

The dye solutions have been exposed to direct sunlight and also a 500-W tungsten filament lamp at a constant voltage of 230 V for about 24 h and have been found to be photo-stable.

We thank Prof. Santi R. Palit for his encouragement and the U.S. National Bureau of Standards and the C.S.I.R. (India) for financial assistance.

Ionizing Radiation and Lightning Hazards

MR. P. J. GILLESPIE has recently questioned the claim that a small radioactive source attached to a lightning conductor can provide protection over a wide radius as a result of ionization of the surrounding air[1]. He points out that if this claim is justified, then users of large sources of ionizing radiations in hospitals and industry may be at considerable hazard from lightning.

A little further simple arithmetic illustrates well the improbability, to say the least, that a small radioactive source could be effective as a lightning conductor. According to Gillespie, a commercially available type has a source of 706 μc. radium 226 and is claimed to give protection over a radius of 100 m. At this distance the gamma-ray dose-rate is 6×10^{-5} mr./h or $1{\cdot}6 \times 10^{-11}$ r./sec. The average background of ionizing radiation (cosmic rays, Earth gamma-rays, etc.) in Britain gives a dose-rate of 100 mr./year or 3×10^{-9} r./sec. In terms of ion density, the natural background gives about 6 ion pairs/cm^3/sec, whereas at 100 m from the radioactive lightning conductor there is an additional 0·03 ion pairs/cm^3/sec. It is difficult to believe that this increase of 0·5 per cent in the ion density can significantly affect the path of a lightning stroke. Furthermore, the background ionization, the mean value of which is given above, varies considerably over the country, probably by a factor of at least two. For example, the granite city of Aberdeen and parts of Cornwall have backgrounds appreciably higher than most other places. Local variations in natural ionization must be considerably larger still. As Gillespie points out, a 3,000-c. cobalt-60 source can produce a dose-rate of 6×10^{-5} mr./h at 60 miles; alternatively, it can double the average background ionization at 3–5 miles. No evidence seems to have been produced that natural or man-made variations in the atmospheric ion density have any effect on the frequency or course of lightning strokes. The *reductio ad absurdum* of the claim that a small radioactive source can significantly increase the efficacy of a lightning conductor is almost complete.

One further important point should be mentioned. Gillespie's letter states that legislation governing the use of the radioactive lightning protection device has been passed under the Radioactive Substances Act, 1960. This surely must be a misunderstanding. To the best of my knowledge, the Radioactive Substances Act, 1960, is concerned entirely with registration, rules, facilities, etc., for the disposal of radioactive wastes and has no clause which could authorize the use of any particular radioactive device.

J. E. ROBERTS

[1] Gillespie, P. J., *Nature*, **208**, 577 (1965).

MR. GILLESPIE's recent communication[1] directs attention to the potential hazard created by the possibility of ionizing radiation attracting a lightning strike during a thunderstorm.

This hazard, if real, is a very grave one, and his letter is very timely, particularly in view of the increasing number of installations of kilocurie cobalt sources in radiotherapy departments. However, the figure he quotes of 0·00006 mr./h does not seem correct, because the natural background of radiation at ground-level, arising partly from cosmic radiation and partly from radioactivity mainly in building materials, gives rise to a radiation-level of about 0·012 mr./h.

It is obviously important for those who are responsible for the design of installations where large amounts of ionizing radiation are given out to know the correct figure.

N. W. RAMSEY

Charing Cross Hospital,
London, W.C.2.

[1] Gillespie, P. J., *Nature*, **208**, 577 (1965).

PROF. ROBERTS's interesting comments on my communication regarding ionizing radiation and lightning substantiate my personal opinion that these devices are probably ineffective; this was one of the possibilities I mentioned originally.

However, it is of interest to note two statements made in sales literature issued by the manufacturers: (i) Their research work has shown that lightning will be effectively attracted if the atmospheric conductivity is doubled. (ii) The positive ions produced by the radiation will be attracted towards the negative cloud base, and in the strong electric field, such as exists immediately preceding or during a discharge, will initiate chain reactions which, by collision, increase the degree of ionization. This suggestion that an 'avalanche' ionization process occurs would, if well founded, answer the criticism that the very low dose-rates and therefore very low ionization would not be effective, as in these circumstances the ion density would be higher than the radiation alone would produce.

In view of the fact that it appears many thousands of these sources have been installed in nineteen different countries over the past eight years, and that many particularly vulnerable buildings, for example, chemical plants, explosive magazines, oil refineries, etc., have probably been fitted with them (at high cost—it may cost more than £2,000 to protect a large building), it seems very desirable to establish conclusively whether or not they are effective.

Regarding Prof. Roberts's statement that he is unaware of any legislation concerning these devices, the Order to which I referred was Statutory Instrument No. 1835, "The Radioactive Substances (Attachments to Lightning Conductors) Exemption Order, 1963", which came into force on December 1, 1963, under Section 2 (6) and (7) of the 1960 Radioactive Substances Act. There is a very similar statutory order applicable to Northern Ireland.

Mr. Ramsey raises an extremely interesting point; that even if a dose-rate of 6×10^{-5} mr./h has no effect on the path chosen by a lightning strike (and this point has still to be conclusively established), possibly some higher radiation dose-rate would.

Arguing by extremes, like Prof. Roberts, but in the other direction, it is generally accepted that intense beams of ionizing radiation can produce a highly conductive path through air, for example, many industries use antistatic devices consisting of radioactive sources which will effectively earth moving machine parts through the conductive path in air produced by the radiation beam. So, if one accepts the fact that ionizing radiation can be used to induce an electrostatic discharge, the pertinent question is, at what dose-rate and under what conditions could this be effective in relation to lightning?

Velocity of Ultrasonic Waves in Single Crystals of Calcium Fluoride

THE elastic constants of crystals are commonly determined by measuring the velocities of propagation of acoustic waves in different principal crystal directions and applying well-known formulae[1]. For crystals of high perfection it has generally been reported that the measured velocity of sound of a given substance is substantially independent of impurity concentration and is a slowly varying function of temperature. There have been relatively few investigations of the dependence of acoustic velocity on impurity density due to the fact that, until recent years, the preparation of highly doped single crystals of high perfection was virtually impossible. We have investigated ultrasonic propagation in a number of calcium fluoride monocrystals grown in the <111> direction by the Czochralski technique. Some of the crystals were of high purity and others were doped with up to 2 per cent significant impurity for experiments on laser action. They were all of comparable perfection, with measured dislocation densities lying in the range 10^4–10^5 cm^{-2}. Samples for measurement were cylinders with opposite ends cleaved and finely polished to plane-parallelism.

The velocities of both longitudinal (v_L) and shear (v_S) ultrasonic waves in the crystals were determined for propagation in the <111> direction and care was taken to determine these quantities to an accuracy of better than 0·5 per cent by means of the pulse-echo technique. Quartz transducers were used and measurements were made by conventional methods. The time markers were calibrated by means of a nickel delay line. Some representative results of room-temperature measurements made with 10 Mc/s input pulses are given in Table 1.

Table 1

Crystal	Impurity	Colour	v_L (km sec^{-1})	v_S(km sec^{-1})
1	Pure	Colourless	6·50	3·98
2	Uranium	Dark pink	6·53	4·06
3	Uranium	Brown	6·67	4·09
4	Samarium	Green	6·44	4·02
5	Neodymium	Light green	6·45	4·03

The values of velocity are taken from a series of measurements on specimens of uniform colour cut from each crystal and the accuracy is believed to be better than 0·5 per cent so that the last figure in each case is significant. The values for pure material closely agree with the results quoted by Gerlich[2]. It seems clear that for crystals of calcium fluoride doped to about 1 per cent with the impurities mentioned in Table 1 the velocities of ultrasonic waves differ from the values for pure material, being greater in some cases and less in others, even though the samples are otherwise of comparable crystal perfection.

We thank the British Council for the award of a travelling scholarship to one of us (Yu. G. S.), G. W. Green of the Royal Radar Establishment for the supply of single crystals and Mr. J. Blitz for discussions about the measurements.

GEOPHYSICS

Carrier of Remanent Magnetization in Certain Red Sandstones

MANY of the palaeomagnetic data which have accumulated during the past 10 years have resulted from extensive measurements on red sandstones, which often possess a stable and measurable component of remanent magnetization. At the present time, the process by which these rocks acquire their magnetization is not fully understood. Thermal demagnetization experiments show that haematite (α-Fe_2O_3) is generally responsible for the stable natural remanent magnetism, and this material occurs in two distinct forms in red sediments. One form is the red pigment, which gives the rocks their distinctive colour and is in the form of a coating on the quartz and feldspar grains and sometimes fills the interstices of the rock; the other form is black crystalline particles ('specularite'). Both these varieties of haematite are capable of carrying the natural remanent magnetism, through the acquisition of either depositional or chemical magnetization. The former process seems most likely to be associated with specularite[1], but the latter could be acquired by the pigment, if it were deposited from circulating iron-bearing solutions, or by the specularite if diagenetic alteration of magnetite to haematite occurred.

Except for field tests, there is no method of distinguishing between depositional and chemical magnetization, and I have attempted the alternative approach of determining whether the pigment or specularite (or both) carries the stable natural remanent magnetism of red rocks, using the technique of chemical demagnetization. This technique has been described elsewhere[2]; briefly, utilizing the fact that the pigment can be chemically dissolved out of the rock sample more rapidly than the specularite particles, the intensity of the natural remanent magnetism of a thin rock disk is measured at stages during treatment with acid; a record is kept of the amount of iron dissolved out during the intervals between measurements, and the point at which the pigment is completely dissolved is noted. A graph can then be drawn showing the decay of natural remanent magnetism and the decrease in iron content, and the proportion of the initial natural remanent magnetism remaining at the point where the pigment is dissolved is an estimate of the lower limit of the contribution of the specularite to the natural remanent magnetism of the rock.

Samples of red and purple sandstones from ten formations have been examined, ranging in age from Jurassic to Pre-Cambrian. With one exception (the Jurassic sample) there is some evidence that the natural remanent magnetism of the formations possesses a certain stability, either from thermal demagnetization, the existence of grouped directions of magnetization remote from the present field or the existence of reversals at a site. Disks of either 2·5 cm or 3·5 cm diameter and from 0·06 cm to 0·3 cm in thickness were used (according to porosity) and the solution carried out at 55° C in concentrated hydrochloric acid, intensity measurements being made with an astatic magnetometer. There is some uncertainty in the amount of haematite extracted at any stage, since the only possible iron measurement is of total iron (ferrous and ferric); it is probably not a serious source of error since the ferrous iron content of red beds is usually small compared with that of ferric iron. It does not affect the main object of the experiments, which is to measure the remaining natural remanent magnetism after the pigment has been dissolved.

Two types of results were obtained, examples of which are shown in Fig. 1. In Fig. 1*a* the pigment dissolves comparatively quickly and about 80 per cent of the original natural remanent magnetism remains at the point when the pigment has dissolved (shown by the vertical broken line); this represents the lower limit to

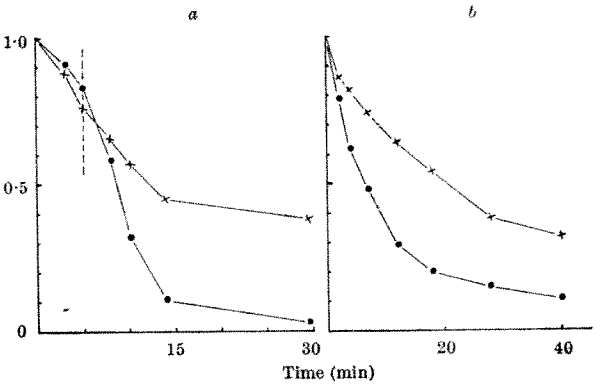

Fig. 1. Decrease of natural remanent magnetism (●) and iron content (×) during acid treatment of samples of red sandstone from (*a*) Moenkopi and (*b*) Lodore (normalized ordinates). The vertical broken line in diagram (*a*) marks the point at which the pigment has all dissolved

the percentage contribution of the specularite to the natural remanent magnetism. Before this point both specularite and pigment are being dissolved and it is uncertain whether the latter also contributes to the initial natural remanent magnetism. Additional information from the graph is that at least 75 per cent of the iron in the rock is in the form of the black particles and that at least 40 per cent of the total iron content is not contributing to the remanence. Results of this type were obtained from six of the ten formations, details of which are shown in Table 1. Except for the Chugwater samples, which came from different sites in Wyoming, the samples were from one site where two samples of the same formation were examined.

Table 1. SAMPLES OF RED SANDSTONES IN WHICH SPECULARITE CONTRIBUTES TO THE NATURAL REMANENT MAGNETISM

Formation and locality	Description of rock	No. of samples	Lower limit to percentage contribution of specularite to natural remanent magnetism
Kayenta, Arizona (Jurassic)	Coarse red-brown sandstone	1	85
Chinle, Utah (Upper Triassic)	Medium red-brown sandstone	1	90
Chugwater, Wyoming (Triassic)	Medium and fine red-brown sandstone	5	80
Moenkopi, Wyoming (Triassic)	,, ,,	2	70
Cutler, Arizona (Permian)	Fine red-brown sandstone	2	30
Supai, Colorado (Permian)	Medium red-brown sandstone	2	70

Where more than one sample of any formation was examined, the figure in the last column is an average value.

A different type of result is shown in Fig. 1*b*. The iron and natural remanent magnetism decay curves are more similar in shape, both decreasing smoothly, and there is usually more or less pigment remaining at the centre of the disk when the natural remanent magnetism has decreased to less than 10 per cent of its initial value. Under the microscope, these samples are seen to contain very little specularite compared with, for example, the Chugwater samples, but all contain varying amounts of pigment. Taken in conjunction with the similarity in the shape of the decay curves for iron and natural remanent magnetism, and the persistence of some of the pigment through to the end of the solution process, this strongly suggests that the pigment is contributing the majority, if not all, of the remanence observed in these rocks. The samples examined which show this type of behaviour are from the Taiguati formation, Bolivia (Permian), Deadwood formation, Wyoming (Mississippian), Lodore formation, Utah (Cambrian), and the Bass limestone (Pre-Cambrian) from two sites in Colorado. The Bass limestone samples are dark red and fine grained, and the samples from the other three formations are rather coarse purple sandstones. There is no significant change in the direction of magnetization of any of the samples

investigated, during the decay of the natural remanent magnetism.

It is concluded from these experiments that the pigment and specularite in red sandstones can both contribute to the natural remanent magnetism; it is not yet known whether they contribute to the natural remanent magnetism in rock in which specularite and pigment are both present, although there is one observation which may be relevant. In those cases where a curve of the type in Fig. 1*a* is obtained, a decrease in the rate of decay of natural remanent magnetism might be expected around the point where the pigment has just dissolved, if the pigment was contributing significantly to the initial natural remanent magnetism. However, in Fig. 1*a* the rate of decay is seen to be faster after the pigment has dissolved, and this is a general feature of this type of result. An explanation of this may be that the pigment is covering the specularite particles and the rate of attack of the acid on the latter will increase as the pigment is dissolved away. In view of these uncertainties, I believe that deductions from these curves should at present be confined to the minimum contribution of the specularite to the natural remanent magnetism, and to qualitative conclusions about the distribution of iron between specularite and pigment.

This work is supported by a grant from the Science Research Council, and I thank Miss E. Nubley for assistance with the measurements.

GEOLOGY

Occurrence of *Ostrea eilatensis*: a New Oyster Species from the Cenomanian of Southern Israel and Egypt

THE Cenomanian sections in Central and Southern Israel are rich in ostreid fauna. The majority of fossil oysters represented are attributed to *Exogyra*; however, I have lately collected many specimens of morphologically variable species, unquestionably referred to *Ostrea*, from various localities in the Negev, Southern Israel.

The material on which the species is based consists of about twenty well-preserved specimens; most of them

a *b*

Fig. 1. *Ostrea eilatensis* sp. nov. Holotype, *HU*. 28427. (*a*) External view of young lower valve (×2). (*b*) Internal view of the same specimen (×1). Lower Cenomanian from the vicinity of Eilat

Fig. 2. *Ostrea eilatensis* sp. nov. External view of imperfect young lower valve, *HU*. 28429. Lower Cenomanian from the vicinity of Eilat. (×1)

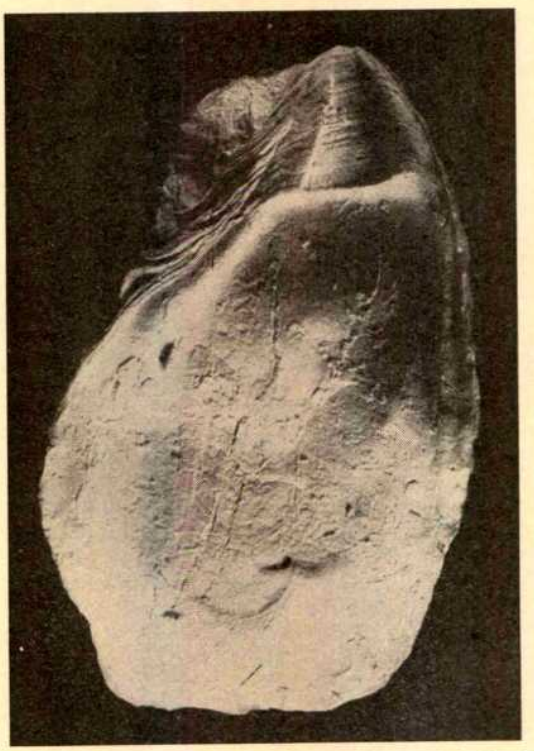

Fig. 3. *Ostrea eilatensis* sp. nov. Interior of adult lower valve, *HU*. 28430. Lower Cenomanian, Ramon. (×1)

Fig. 4. *Ostrea eilatensis* sp. nov. Holotype, *HU*. 28428. Interior of young specimen of upper valve. Lower Cenomanian from the vicinity of Eilat. (×1)

are of the lower valve. Representatives of the species are almost always embedded in soft marly strata.

The shell is subtriangular, inequivalve and inequilateral. The outlines of the valve are generally rounded, except those from the early stages which have a straight posterior border. The ligamental grooves are broad and shallow. The lower valve is convex and the umbo acutely angulated and prominent. Sculpture in the early stages of growth consists of longitudinal, densely crowded, numerous, somewhat sinuous rounded ribs, fanning out from the umbo; the number of the ribs is increased toward the

margin by branching and by the interpolation of new ribs. The surface is marked with concentric, somewhat imbricating growth lines that cross the ribs. Owing to the peculiar radial sculpture, the margin is marked by fine, rather obscure, crenulations. The early stages of growth possess a relatively small area of attachment, in contrast to the adult specimens, which are characteristically totally attached. An average-size specimen measures about 34 mm in length and 22 mm in greatest breadth. The corresponding dimensions of the largest collected specimen are 90 mm and 50 mm.

The upper valve is shorter than the other. It is flat or very slightly convex, and its surface is commonly marked only by prominent lines of growth. The interiors of both valves have deeply excavated sub-oval muscular impressions, situated on the posterior side, below the middle of their height, and the margins of the interior of the shell are elevated and slightly crenulated.

A great amount of variation is shown by this species, both in its form and in its sculpture; the fan-like fashion of radial ribbing on lower valve is transformed into coarse granulation in medium-sized specimens and the radial sculpture is totally eliminated in the adult specimens. When the shell is about half grown, the lower valve becomes less regular in form and attains its deepest excavation.

This well-marked species seems to have no close relatives in European and American Cenomanian faunas. It seems to me to be more nearly related to *Ostrea alicula* Hamlin, which has been reported from various Tethyal Aptian formations. The latter is distinguished chiefly by its smaller size, its more regular form, its more pointed apical region and the smaller number of radiating ribs on lower valve.

The specific name is derived from Eilat, where several of the best specimens studied were found.

This species seems to be confined to the Lower Cenomanian. It is common and widely distributed in Lower Cenomanian strata of the Ramon erosion cirque and the Eilat region, Southern Israel. Specimens collected from Cenomanian of the Gebel Minshera monoclinal structure of Northern Sinai, Egypt, are in good agreement with these from the type locality and Ramon.

Salt Temperature: a Fundamental Factor in Salt Dome Intrusion

IN a previous article[1], I dealt with the emplacement of igneous masses (volcanic plugs, granite batholiths, diamond pipes, and serpentine bodies), salt domes, and such related bodies as mud volcanoes, ice piercements or pingos, and frost boils. In reviewing the subject for presentation at a recent symposium on salt domes in New Orleans, Louisiana[2], it dawned on me that heat is a very important factor and may actually initiate salt intrusion.

The prime motivating force for all intrusions is the weight of the overburden, or geostatic load, and in the case of salt, this is supplemented by buoyancy. In both, the force of gravity is the sole source of driving energy involved. Plastic flow of salt only occurs after deep burial—usually in excess of 15,000 ft. At shallower depths, it behaves as a competent rock and can withstand the geostatic load or may be folded together with the rock strata above and below without any evidence of plastic flow. Thus, salt domes are never found in areas where the evaporites have not been buried in excess of 15,000 ft. On the other hand, evaporites are unknown as metamorphic rocks[3], a fact which suggests that all traces

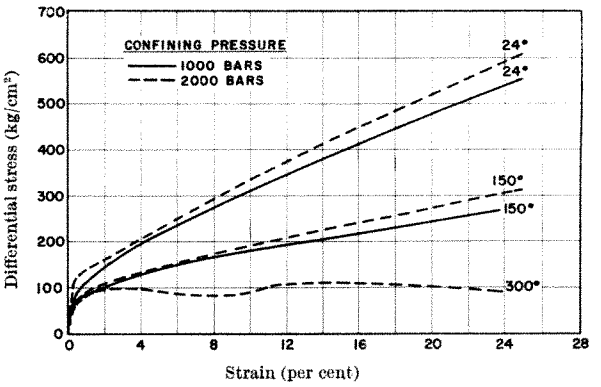

Fig. 1. Stress-strain curves for halite single crystals deformed dry in compression at 1,000 and 2,000 bars confining pressure and at different temperatures. Redrawn after J. Handin and R. V. Hager, jun., "Experimental deformation of sedimentary rocks under confining pressure: tests at high temperature"; *Amer. Assoc. Petrol. Geol. Bull.*, **42**, 2901 (1958)

of evaporites are expelled from sedimentary sequences by deeper burial.

A recent article by Kent[4] clearly demonstrates that salt has been extruded at the surface in several salt domes in Iran and has flowed downhill in the form of glaciers. It is physically impossible for salt to flow at the surface at atmospheric temperature and pressure. Salt is crystalline and has a hardness of 2·5, and as such would behave very much like limestone or any other competent rock. The only explanation for the glaciers would appear to be that the salt must have been hot when it was extruded.

The importance of temperature in salt dome tectonics has received very little consideration in the past. It is well known that temperature, as well as pressure, increases with depth of burial, but what sort of temperatures can be expected? A recent well[5] drilled by Amerada in the Gulf Coast salt dome area, Victoria County, Texas, has recorded a rock temperature in excess of 520° F at a depth of about 23,000 ft. On the evidence of palynology[6], the age of the Gulf Coast salt is Late Triassic to Early Jurassic and these strata lie at greater depth and at correspondingly higher temperature. It can reasonably be assumed that temperatures well above 500° F must have existed in the source salt beds from which the salt domes originated at the time of intrusion.

One of the earliest experiments on the effect of temperature on salt was by Cermak[7], who discovered that, by heating salt above 200° C (392° F), halite crystals can be bent quite easily. Above 200° C, salt flows without rupture. In 1958, Handin and Hager[8] published the results of laboratory experiments on the behaviour of salt at high pressures and temperatures (Fig. 1). Note that pressure has very little effect on yield stress, but that temperature is extremely important, and greatly reduces the ultimate strength and eliminates work hardening at 300° C (572° F). Both these conditions are operative at depths exceeding 25,000 ft., and with a pressure gradient of only about 100 kg/cm² (1,400 p.s.i.) salt behaves as a true plastic and flows indefinitely. It would appear that once salt has been heated above 400° F it becomes soft and plastic and is mobile. This plasticity can exist during the entire process of intrusion and even during extrusion at the surface. Thus, at the time of extrusion, salt can flow by simple gravity like a glacier—so long as it remains hot.

As pointed out by Orowan[9], fluids (liquids, glasses, and most non-crystalline materials) exhibit Newtonian viscosity, but crystalline materials behave as plastics and according to Andradian law. For an ideal plastic, the creep rate is zero until the stress approaches the creep limit. No deformation occurs until the yield point is reached, then any deformation at any velocity can result from the fixed stress. The salt does not flow: it moves

like a plug—very much like toothpaste being squeezed out of a tube.

In summary, the first essential for intrusion to result is that there must be a plastic medium (salt, mud or clay, ice, magma) and this must occur in the form of extensive sheets. In the case of salt, before buoyancy can begin to play any role, it must be buried at a depth of from 2,000 to 5,000 ft. Salt starts to become plastic below 12,000 ft. on account of pressure, and at about 25,000 ft. it becomes mobile on account of temperature. When it is mobile, it behaves hydrostatically and, as the surface load is never in exact balance, it will move laterally to places of less overburden pressure, where piercement or doming occurs. This state of balance is extremely delicate. Once initiated, flow would continue until the supply is exhausted.

The second requirement, then, is that there must be an imbalance in geostatic load distribution to initiate horizontal hydrodynamic flow. This lateral flow can only be due to geostatic load, but once piercement occurs, geostatic load plus the ever-increasing effect of buoyancy will cause the intrusive mass to rise rapidly through the overlying strata. Buoyancy only becomes a powerful force as the height of the intrusion increases to large proportions. At first, when no vertical relief exists on top of the evaporite layer, buoyancy is zero and piercement of the overlying strata cannot be caused by buoyancy alone. In the case of salt, buoyancy is known to be positive, but for magmas, it may be positive (up) or negative (down), depending on the density difference. Accordingly, buoyancy is not a requirement for intrusion, but is a modifying effect. Thus, intrusion of a very dense magma, such as kimberlite, can also occur.

As the salt moves into shallower overburden depths with their reduced geostatic load and lower near-surface compaction, the diameter of the stock generally increases. When the hydrostatic pressure of the salt (or magma) column balances the geostatic overburden pressure of the rock column on the source reservoir, or when the supply is exhausted, upward movement will cease. Thus, heavy basaltic magmas and even salt domes frequently do not reach the surface. It is postulated that the intrusive salt or magma should spurt into joints or fractures in the overlying rocks, speedily rising toward the surface, slowing down on reaching shallower depths (of less than 5,000 ft. in the case of salt), so that gentle flow may occur at the surface. Where the salt has reached the surface, it can flow out on the surface, or downhill like a glacier at the time of extrusion, but once it cools, it can only move downhill by very slow solid creep. This is in no way a measure of the rate of intrusion.

It should be pointed out that isopach thinning of a formation over a dome is not evidence of uplift during sedimentation unless erosional thinning can be demonstrated: thinning can also occur by stretching or by compaction of the strata above a dome at the time of intrusion.

In conclusion, heat is extremely critical for salt intrusion to result, and the energy driving the motion is gravitational potential energy derived primarily from the weight of the overburden, or geostatic load, and supplemented by the buoyancy effect caused by a density differential.

Olivine Nodules in a Phonolite of the East Otago Alkaline Province, New Zealand

Numerous olivine nodules were recently reported by Sang Lyen[1] in a cossyrite phonolite flow from one of the lesser centres peripheral to the Dunedin Volcanic Complex, of Upper Miocene to Lower Pliocene age. The nodules are " . . . of varying size, widely scattered in the flow. Small nodules, a fraction of an inch across, may be found distributed widely, while larger types are mainly concentrated in the medial layers of the flow. . . ." Blocks up to 20 in. long were found.

The nodules are similar in appearance to those frequently found in basic lavas of alkaline affinities[2,3] and have similar mineralogy: olivine ($\beta = 1{\cdot}672 \pm 0{\cdot}002$), optically neutral, often with undulose extinction in wide subparallel bands; clinopyroxene ($\beta = 1{\cdot}685 \pm 0{\cdot}002$), $2V = 58°$ (ref. 1), bright green in hand specimen, with occasional exsolution lamellae of orthopyroxene; orthopyroxene ($\beta = 1{\cdot}672 \pm 0{\cdot}002$), very high negative $2V$; spinel ($n = 1{\cdot}80 \pm 0{\cdot}005$ (in O.U. 17738) and $1{\cdot}83 \pm 0{\cdot}01$ (in O.U. 17737)), brown interstitial grains, sometimes with narrow reaction rims against silicate.

The volume of exposed trachytes, phonolites, and salic pyroclastics accounts for about a quarter of the Dunedin Complex as a whole, while types intermediate between these and the basalts and basanites represent less than 5 per cent. On the other hand, trachytic lavas and pyroclastics made up almost all the initial eruptive phase of the main volcano, and over half the lavas of the third main eruptive phase were phonolite (estimates derived from incomplete computations by the late Prof. W. N. Benson).

In many continental alkaline provinces (such as East Africa) the overall volume of salic lavas and pyroclastics equals or exceeds that of associated basic eruptives, while flows of intermediate composition are but sparsely represented, as they are in the Dunedin Complex. Implicit in some recent work on the subject[4–7] is the idea that in such regions a mechanism other than fractional crystallization is required to account for the disproportionate amounts of basic, intermediate and salic lavas.

Olivine nodules in alkaline basalts are considered by many (see, for example, refs. 2 and 3) to represent subcrustal material. Assuming this to be a valid hypothesis, the occurrence of similar nodules in this phonolite would be evidence that it too was generated at sub-crustal levels.

Other evidence that some phonolite may originate at great depths is less directly provided by recent investigations of strontium isotope ratios in carbonatites and other rocks from alkaline igneous complexes[8,9]. The results are shown to be consistent with at least a sub-sialic source, both for the carbonatites and for the associated, comagmatic, igneous rocks. Phonolitic activity is not infrequently associated with carbonatite centres, as in East Africa, where field associations at least suggest that it may well be genetically related to carbonatite (see ref. 10), and could therefore have been generated from a similar deep-seated source.

I thank Prof. D. S. Coombs for helpful advice and discussion.

CHEMISTRY

Tricarbazyl

OXIDATION of carbazole with potassium permanganate in boiling acetone was reported in 1921 (ref. 1) to yield two crystalline products, (*A*) and (*B*), and an amorphous product. One of these crystalline products, (*A*), was later shown[2] to be 9,9′-dicarbazyl, and the other, (*B*), which was thought[1] to be a dicarbazyl on the basis of a cryoscopic molecular weight determination in benzene, was shown not to be identical with synthetic specimens of 1,1′- (ref. 3), 3,3′- (ref. 4) and 3,9′- (ref. 5) dicarbazyls. It was, however, proposed[6] that (*B*) might be either 1,3′- or 1,9′-dicarbazyl.

A recent paper[7] describing investigations of the oxidative dimerization of carbazole in various solvents prompts this report of structural investigations which have been carried out on the aforementioned compound (*B*), which has been prepared from carbazole by a method previously described[1].

The mass spectrum (mass spectra were recorded on an A.E.I. *MS* 9 spectrometer by Dr. J. M. Wilson) of compound (*B*) exhibits a molecular ion peak at $m/e = 497$, which, therefore, contrary to the previous proposal[1], shows it to be a tricarbazyl for which structure (I) is proposed on the basis of the following evidence.

(I)

(*a*) The mass spectrum of compound (*A*), 9,9′-dicarbazyl[2], which has a molecular ion peak at $m/e = 332$, shows the expected very easy fragmentation across the N—N bond to give a base-peak at $m/e = 166$. By comparison, the mass spectrum of (*B*) indicates, as well as a molecular ion peak at $m/e = 497$, the very easy loss of one carbazyl group (presumably by N—N bond scission as occurred in 9,9′-dicarbazyl) to give a base-peak at $m/e = 331$. Further fragmentation of the stronger C_3—N bond then affords much weaker peaks at $m/e = 167$ and 166.

(*b*) The infra-red spectrum (infra-red spectra were recorded in 'Nujol' on a Perkin Elmer model 237 spectrophotometer) of (*B*) shows no absorption in the N—H stretching region, indicating that the carbazole N-atoms must take part in the bonds between the three carbazole units. The complete spectrum is also very similar to that of 9,9′-dicarbazyl, but, unlike the latter spectrum, it exhibits a medium-strong band at $\nu_{max} = 812$ cm^{-1} and a weak band at $\nu_{max} = 879$ cm^{-1}, indicative of a 1,2,4-tri-substituted benzene nucleus[8], which therefore supports the attachment of the third carbazole unit to the 9,9′-dicarbazyl unit in (*B*) at either C_2 or C_3.

(*c*) That this linkage is between N—C_3 as shown in (I) and not between N—C_2 is supported by the observations[9] that C_3 in carbazole is more reactive than C_2.

Attempts to verify chemically structure (I) by selective reductive cleavage of the N—N bond to afford carbazole and 3,9′-dicarbazyl[5] have not been successful, probably due to the low solubility of (*B*) (ref. 1). Treatment with concentrated hydriodic acid at 150° C in a sealed tube for 15 h gave, contrary to previous observations[2], only carbazole.

Crystal Structure of the Benzene *tris*(*o*-Phenylenedioxy) Phosphonitrile Trimer Complex

A DESCRIPTION of the inclusion compound *tris*(*o*-phenylenedioxy) phosphonitrile trimer has already been reported[1] which includes some preliminary crystallographic data and a short discussion of the possible arrangements of the molecular architecture. This communication describes a partial structure determination in two dimensions of the complex with benzene.

The crystals were hexagonal, unit cell $a = 11{\cdot}68$ Å, $c = 10{\cdot}077$ Å; space group either $P6_3$ or $P6_3/m$. The measured density of 1·395 g/c.c. is consistent with two molecules of the trimer and about one benzene molecule in the unit cell. The intensities of seventy-four independent $hk0$ reflexions were visually estimated, corrected for Lp factors and used to calculate the Patterson projection $P(u,v)$.

As reported in ref. 1, the two trimers must either be sited on the six-fold axis or one on each of the triad axes, but simple packing considerations show that only the sites on the three-fold axes lead to a structure containing suitable channels. The vector line of the *o*-phenylenedioxy group was obtained from the Patterson map, and a Fourier map based on a trial structure showed well-resolved atoms of the trimer arranged so that six trimers form one channel per unit cell around the benzene molecule which is sited at the origin. Initially the R value was high (> 40 per cent), but marked improvement was obtained (R fell to 21 per cent) when the trimer was moved through a small angle around the triad axis (the

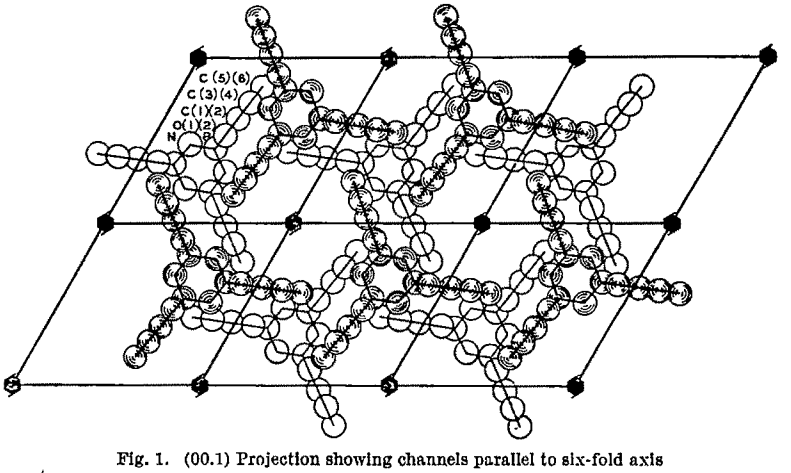

Fig. 1. (00.1) Projection showing channels parallel to six-fold axis

calculated structure factors are particularly sensitive to the azimuthal setting of the trimer) and further improvement to 18·6 per cent was obtained by small independent movements of the individual atoms of the trimer. It was assumed throughout that the planes of the phenylenedioxy groups were parallel to c, but only a least-squares refinement of three-dimensional data would prove this.

The effect on the diffraction transform was calculated for various orientations of the benzene molecule on the six-fold axis, but as the molecule exhibits rotational disorder its position is essentially indeterminate. The best position corresponded to the long axis of the benzene molecule parallel to or within 20° of the six-fold axis. Orientations where this axis was perpendicular to the plane of the molecule or to a C—C bond were eliminated because the long dimension of the molecule ~ 7 Å exceeded the diameter of the channel.

The atomic parameters of the trimer are:

	x	y	B
P	0·543	0·357	4·74
N	0·518	0·209	4·74
O (1) (2)	0·466	0·373	4·74
C (1) (2)	0·363	0·388	5·69
C (3) (4)	0·266	0·409	5·69
C (5) (6)	0·170	0·423	5·69

The packing of the trimers is such that channels, of internal diameters about 6 Å, are created as shown in Fig. 1 with the planes of the *o*-phenylenedioxy groups forming the channel walls. There is one channel per unit cell which is continuous throughout the structure and in this respect there is a close similarity to the channel structure of tri-*o*-thymotide.

Note. Dr. L. A. Siegel and Dr. J. H. van der Hende (American Cyanamid Co.) have recently completed a three-dimensional structure determination of this complex. The results, which were presented at the American Crystallographic Association, Gatlenburg, Tennessee, June 1965 (to be published in *J. Amer. Chem. Soc.*), are in agreement with ours.

Fluorescence Spectrum of Phenol Vapour

INVESTIGATIONS of the fluorescence spectra of polyatomic molecules in the vapour phase suffer from the obvious difficulty that a suitable exciting source is generally not available. For this reason the fluorescence spectra of a very few polyatomic molecules have been reported so far. In this direction attempts have been made by many workers[1-3] to study the fluorescence spectra of monosubstituted benzenes using condensed sparks with different electrodes as suitable exciting sources.

Following the above technique, phenol vapour was excited by condensed iron spark rated 0·25 kW at 15,000 V with a condenser of capacity 0·005 mF kept in the circuit parallel to the spark gap. The complete experimental arrangement has been described elsewhere[4]. The spectrum was photographed on Kodak 'II 0' plates using a Hilger medium quartz spectrograph. An exposure of 80 h was used to gain sufficient intensity.

The fluorescence spectrum of phenol lies in the region 2750–3100 Å and consists of about fifty bands. The bands, except for a few, are sharp. A weak continuum has been found to overlap the entire spectrum. The wave-numbers (in vacuum) of these bands, with their approximate intensities and assignments, are collected in Table 1. The figures in parentheses are the difference in wave-numbers between the observed and the assigned values.

Table 1. FLUORESCENCE BANDS OF PHENOL

v, very; *s*, strong; *m*, medium; *w*, weak; *d*, diffuse.

To explain the gross structure of the bands, phenol has been taken to belong to C_{2v} point group. The electronic transition involved is $^1B_1$–$^1A_1$, which is allowed from symmetry considerations. The 0–0 band and the bands involving totally symmetric vibrations, a_1, are expected to appear strongly. The vibrations b_1 and a_2 will give rise to weak bands. Transitions involving single quantum of b_2 vibrations are forbidden. In fluorescence spectra the intensity of the 0–0 band is generally reduced by self-absorption. The weak band at 36,349 cm^{-1} is taken as the 0–0 band. This is in agreement with the measured value in the emission spectrum[5]. The bands at 36,108, 35,823, 35,725, 35,528, 35,348, 35,314, 35,093, 34,982 and 34,761 cm^{-1} are separated from the 0–0 band by 241, 526, 624, 821, 1,001, 1,033, 1,256, 1,367 and 1,588 cm^{-1}. They are taken as the fundamental vibrations of the ground state.

All the vibrations, except 241 cm^{-1}, have been found to obey the symmetry properties of C_{2v} point group. The vibration 241 cm^{-1} which is involved in a very weak band at 36,108 cm^{-1} has also been reported in the emission[5] and absorption[6] spectra. This frequency has been assigned to b_2 symmetry type following the assignment of the corresponding frequency 242 cm^{-1} in the Raman spectrum[7]. This vibration is not expected to appear as a single quantum in the electronic spectrum. The occurrence of this vibration suggests that C_{2v} symmetry does not hold rigorously for this molecule, but is only approximately true, and the molecule probably belongs to some lower symmetry group.

A comparison of the fundamental ground state vibrations of phenol as observed in the Raman, infra-red[7], near ultra-violet absorption, emission and fluorescence spectra is given in Table 2.

Table 2. COMPARISON OF THE FUNDAMENTAL GROUND-STATE VIBRATIONS OF PHENOL

Raman	Infra-red	Near ultra-violet: Absorption	Near ultra-violet: Emission	Near ultra-violet: Fluorescence	Assignment
242		245	244	241	b_2 X-sens. bend. o.p.
531	531	527	526	526	a_1 X-sens. bend. i.p.
617	618	623	621	624	b_1 ring bend. i.p.
814	812	824	808	821	a_1 X-sens. stetch.
1,000		999	1,002	1,001	Ring
1,024	1,025		1,021	1,033	a_1 CH bend. i p.
1,253	1,253		1,261	1,256	a_1 X-sens. stetch.
				1,367	COH bend. i p.
1,603	1,604			1,588	a_1 ring stetch.

i.p., In plane. o p., Out of plane.

In addition to the main bands, some strong bands on the longer wave-length side, and weaker bands on the shorter wave-length side, have also been observed. They involve difference frequencies of −35, −61, −221 and 40 cm^{-1}.

I thank Prof. N. L. Singh, Department of Spectroscopy, Banaras Hindu University, for helpful discussions, and the Council of Scientific and Industrial Research for the award of a research fellowship.

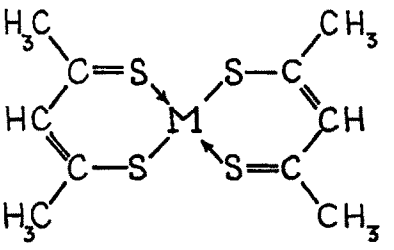
Synthesis of Transition Metal Complexes of the Unknown Chelate, Dithioacetylacetone

ACETYLACETONE (acacH), from which the unknown chelate, dithioacetylacetone, can theoretically be obtained by substitution of two oxygen atoms with sulphur, is one of the most versatile bidentate chelates known[1]. In the enol form the hydroxylic proton can readily be replaced by a great many metal ions to give neutral complexes of the composition $M(acac)_n$. The co-ordination number of the metal is usually $2n$ and the resulting stereochemistry is tetrahedral, square planar or octahedral, although examples of square antiprismatic and square pyramidal co-ordination are known. The bonding to the metal is invariably through the two oxygen atoms, although it has been shown[2] recently that the α-carbon atom can bond to platinum in the compound trimethyl (acetylacetonyl)-2 : 2′ bipyridyl platinum (IV). Certain of the metal acetylacetonates undergo reactions characteristic of aromatic systems and these have been reviewed by Prof. Collman[3].

Recently, it has become apparent that bidentate sulphur chelates confer highly novel stereochemical, magnetic and spectral properties on transition metal ions which are due, in part, to the ease with which sulphur can participate in π-bonding with the central metal ion. We have been concerned, in this laboratory, with the chemical and physical properties of transition metal *N,N* disubstituted dithiocarbamates and, in particular, with the $^2T_2$–$^6A_1$ spin equilibrium exhibited by the iron (III) derivatives[4]. As a logical extension of these investigations we report here our attempts to combine the great versatility of acetylacetone with the remarkable properties so often possessed by transition metal complexes in which co-ordination is through sulphur atoms.

It should be noted that, although attempts have been reported for the synthesis of dithioacetylacetone by reacting a solution of acetylacetone in ethanolic hydrogen chloride with hydrogen sulphide, none were successful[5–7].

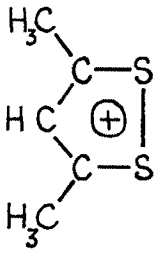


(I)

The main product of the reaction is a colourless, crystalline dimer which has been shown[8], by nuclear magnetic resonance spectroscopy and mass spectrometry, to have the structure (I). The dimer is characterized by exceptional resistance to chemical attack, and its conformation precludes chelating properties. Chaston *et al.*[9,10] have investigated a variation of the foregoing reaction, and have succeeded in isolating several new monothio-β-diketones, from which can be prepared brown, diamagnetic nickel complexes. In no case, however, were dithio-β-diketones prepared.

Isolation of the dimer (I) establishes that both oxygen atoms of the parent diketone are, in fact, substituted by sulphur atoms in the reaction medium. Accordingly, it seemed possible that, if the reaction were carried out in the presence of a suitable metal ion, dimer formation might be sufficiently inhibited for dithioacetylacetone to be isolated in the form of its metal complexes.

This experimental procedure has proved to be most effective and has led us to the successful synthesis of the compounds $Co^{II}(Sac\ Sac)_2$*, $Ni^{II}(Sac\ Sac)_2$, $Pd^{II}(Sac\ Sac)_2$ and $Pt^{II}(Sac\ Sac)_2$. These are crystalline, non-electrolytes in nitrobenzene, soluble in organic solvents but not in water, and are monomeric in the vapour state.



The solids are intensely coloured giving dark-red (Co^{II}, Ni^{II}), bright-red (Pd^{II}), or purple (Pt^{II}) solutions in benzene. $Co^{II}(Sac\ Sac)_2$ is paramagnetic with a magnetic moment, $\mu_{eff} = 2{\cdot}3$ Bohr magnetons, which is independent of temperature between 80° and 300° K. The nickel, palladium and platinum complexes are diamagnetic. A square planar co-ordination of the central ion by four sulphur atoms is therefore favoured as in structure (II).

(II)

Proof for the proposed formulation of these compounds is obtained from proton magnetic resonance spectroscopy and mass spectrometry. Thus Ni^{II} $(Sac\ Sac)_2$ exhibits just two proton resonance peaks in the expected ratio of 1 : 6. The mass spectra are characterized by strong parent ions at m/e = 321 [$^{59}Co^{II}(Sac\ Sac)_2$], m/e = 320 [$^{58}Ni^{II}(Sac\ Sac)_2$], m/e = 370 [$^{106}Pd(Sac\ Sac)_2$], and m/e = 457 [$^{195}Pt(Sac\ Sac)_2$] derived by electron loss from structure (II). The only other significant peaks in the spectra are due to ions at m/e = 131 which may have the

* The commonly accepted abbreviation for the acetylacetonate anion is 'acac'. We therefore suggest that 'Sac Sac' would be a suitable abbreviation for the dithioacetylacetonate ligand. On this basis the abbreviation for the monothioacetylacetonate ligand would be 'Sac ac'.

(III)

resonance stabilized (aromatic) dimethyl dithiolium cation structure as shown in III.

A preliminary examination of the chemical behaviour of the new complexes has indicated that they are not attacked by boiling alkali, slightly attacked by concentrated hydrochloric acid and decomposed by oxidizing acids. $Co^{II}(Sac\ Sac)_2$ is oxidized irreversibly by air when dissolved in pyridine, but in the absence of air a green solution is obtained in which pyridine molecules are probably co-ordinating to the central cobalt ion by way of the vacant axial positions.

Our attempts to isolate the parent ligand (Sac Sac H) from the metal complexes have, so far, proved unsuccessful.

All the compounds are characterized by electronic spectra rich in absorption bands (see Table 1). Those at lowest energies may be assigned to internal transitions within the *d* shell of the central ion. Those at higher energies arise from metal to ligand, ligand to metal and ligand to ligand electron transitions. We are, at present, carrying through molecular orbital calculations, in the Hückel approximation, by the procedures of Gray and Ballhausen[11], to define the transitions in greater detail.

Table 1. ELECTRONIC SPECTRUM OF $[Co^{II}(SAC\ SAC)_2]$

Wave-length (mμ)	Energy (cm^{-1})	Molar extinction coefficient	Solvent
1,480	6,750	20	Carbon disulphide
920	10,870	30	,, ,,
572	17,500	4,000	Benzene
462	21,600	3,200	,,
415 sh.	~24,000	~5,000	,,
360 sh.	~28,000	~15,000	,,
341	29,400	14,000	Carbon tetrachloride
273	36,600	28,000	,, ,,
249	40,100	~20,000	Methanol
224	44,600	~30,000	,,

The main absorption bands in the infra-red region are listed in Table 2. A detailed assignment of these bands is being secured by a normal co-ordinate analysis, based on a detailed knowledge of the molecular geometry. The preliminary results of a single crystal X-ray study[12] of $Co^{II}(Sac\ Sac)_2$ show that the crystals are orthorhombic with unit cell dimensions $a = 15{\cdot}6_4$ Å, $b = 14{\cdot}3_5$ Å, $c = 6{\cdot}0_5$ Å, and there are four units of composition Co(Sac Sac)$_2$ per unit cell. The space group is either *Cmca* or *C*2*cb*. For both space groups the cobalt atoms must be in special positions which are compatible with the square planar formulation. A tetrahedral cobalt environment is not consistent with the centrosymmetric space group nor, of course, the observed magnetism.

Table 2. SOME CHARACTERISTIC INFRA-RED BANDS OF DIVALENT METAL DITHIOACETYLACETONATES

Compound	Bands (cm^{-1})					
$[Co^{II}(Sac\ Sac)_2]$	1,490 s, br	1,157 s	1,005 m	840 s	740 s	550 m
$[Ni^{II}(Sac\ Sac)_2]$	1,485 s, br	1,159 s	1,012 m	833 s	750 s	557 m
$[Pd^{II}(Sac\ Sac)_2]$	1,485 s, br	1,150 s	1,010 m	830 s	750 s	550 m
$[Pt^{II}(Sac\ Sac)_2]$	1,485 s, br	1,155 s	1,010 m	835 s	750 s	550 m

The preparation of these compounds provides an excellent example of the important part which can be played by metal atoms in achieving the synthesis of normally inaccessible molecules. It seems possible that metal-ion-directed reactions, of a type similar to that described here, may well prove to be important in many biosynthetic processes involving sulphur.

Reaction of Glutarimide with Phosphorus Pentachloride to form Chlorinated Pyridines

THE reaction of glutarimide with phosphorus pentachloride to give 2,3,6-trichloropyridine[1] yielded a material that was found to be quite impure. The infra-red spectrum of the crude product suggested that other chlorinated pyridines were also present.

Lochte *et al.*[2] described the preparation of 3- and 4-*cyclo*pentyl-2,5,6-trichloropyridines using the appropriately substituted *cyclo*pentyl-glutarimides and phosphorus pentachloride. They did not indicate whether other products were present. Lochte and Wheeler[3] later found that the pyridine derivative formed from 3-*cyclo*pentylglutarimide was impure, and they deduced from elemental analyses and molecular refraction data that the crude product was a mixture of 4-*cyclo*pentyl-2,6-dichloro- and 4-*cyclo*pentyl-2,3,6-trichloropyridines.

The crude product from our sealed-tube reaction was submitted to column chromatography on alumina using *n*-hexane as the developing solvent, and three pure compounds were isolated: 2,3,5,6-tetrachloropyridine, m.p. 89° (ref. 4); 2,3,6-trichloropyridine, m.p. 68° (ref. 1), and 2,6-dichloropyridine. The solution infra-red and ultra-violet spectra of these materials were identical with those of the known compounds. The pyridine derivatives were eluted from the alumina column with good separation and in the order given. 2,3,5,6-Tetrachloropyridine has not previously been reported as a product of this reaction.

The effects of time and temperature on the course of the reaction were studied and the data are shown in Tables 1 and 2.

Table 1 shows that a twelve-fold increase in time beyond 20 min has no effect on the total conversion to pyridine derivatives at the lower temperatures. In the case of the individual chlorinated pyridine derivatives, there seems to be a decrease in 2,6-dichloro- and an increase in 2,3,5,6-tetrachloropyridines at 100° C, but the changes are only slight. At 270° C, the increased time allowed for the reaction resulted in considerable alteration in the proportion of products.

When the temperature was increased, as shown in Table 2, the conversion to chlorinated pyridines increased slowly. The distribution of products also changed. Dichloropyridine showed a slow decline, trichloropyridine seemed to show a rise at 100° C followed by a steady decrease, and tetrachloropyridine showed a general increase. Pentachloropyridine did not appear until the reaction temperature reached 270° C, and then only a

270	—	0	14	61	25

* The confidence limits are expressed at the 95 per cent level of significance. The values at 55° C and 100° C are the averages of all the determinations at these temperatures in Table 1; those at 125° C and 150° C are for a reaction time of 20 min. The values for 270° C represent 7- and 24-h reactions in that order.

† See Table 1.

very small amount was formed. However, as indicated in Table 1, the proportion of the penta- derivative increased markedly with a four-fold increase in time beyond 7 h.

These results are interpreted in the following way:

As the formation of II from I is taking place, the resulting phosphorus oxychloride also reacts with I and II. The net result of this simultaneous reaction involving phosphorus oxychloride is to effectively remove a portion of I and II from subsequent conversion to pyridine derivatives. When phosphorus oxychloride was used as a solvent for glutarimide and phosphorus pentachloride in this reaction, no chlorinated pyridines were formed. This tends to support the suggestion that the oxychloride does remove I and/or II from further reaction. When the temperature of the reaction is increased, the rate of chlorinated pyridine formation is increased relative to the rate of formation of by-products.

The nature of the by-products has not been investigated. However, when treated with water, the resulting compounds cannot be extracted by carbon disulphide. This suggests that the compounds represented by III are phosphorodichloridic acid derivatives. These are easily hydrolysed by water to give water-soluble phosphoric acid derivatives.

Compound IV, or a tautomer of IV, may be transformed to chlorinated pyridines by a successive series of chlorinations and dehydrochlorinations. The route to 2,6-dichloropyridine can be shown to involve the least number of steps, and consequently, is probably the first pyridine derivative formed.

Chlorination of the fully aromatic ring does not occur until the temperature of the reaction is increased. At 100° C and 20 min, it can be demonstrated that 2,6-dichloropyridine does not react with elemental chlorine. However, at 180° C and 50 h, chlorination of this compound with elemental chlorine does take place to give some 2,3,6-trichloro- and *sym*-tetrachloropyridines. At 285° C and 50 h, all of the chlorinated pyridines are almost quantitatively converted to pentachloropyridine.

At low temperatures, phosphorus pentachloride seems to be essential for the formation of higher chlorinated pyridines in this reaction. However, as the temperature of the reaction is increased, chlorination of the pyridine ring becomes an increasingly important factor in the final distribution of products.

The elemental chlorine required for these reactions is probably furnished by phosphorus pentachloride; at elevated temperatures, the pentachloride decomposes to form an equilibrium mixture with the trichloride and chlorine[5].

Radiolysis of Monomethylhydrazine

IN an investigation of the effects of ionizing radiation on rocket fuels the radiolytic decomposition of monomethylhydrazine has been studied to determine whether the generation of radiolytic gases can be suppressed by the addition of free radical scavengers. The experiment consisted of preparing degassed specimens of monomethylhydrazine with and without free-radical scavengers, gamma-irradiating them with cobalt-60 to $8{\cdot}5 \times 10^6$ rads at 22°–25° C, and analysing the non-condensable gaseous products by gas chromatography.

The 'anhydrous' monomethylhydrazine used contained less than 2 per cent by weight of water and amines (Olin Mathieson Chemical Corporation). There is no reason

to believe that the water acts as a free-radical scavenger to affect the radiolytic decomposition. Water is actually combined with the solvent as CH_3NHNH_3OH, and this undergoes little basic dissociation. Furthermore, Baxendale and Mellows[1] have found that water at a concentration of 3 per cent in methanol does not scavenge radiolytic free radicals originating from the methanol.

The monomethylhydrazine and its solutions were protected from air-oxidation by a nitrogen atmosphere. Methyl methacrylate, pentadiene-1,3 and carbon tetrachloride were used as free-radical scavengers[2] at the large concentration of 5 per cent by volume. The scavenger 1,1-diphenyl-2-picrylhydrazyl could not be used in monomethylhydrazine since its solution slowly generated gas.

The radiolysis cell was a 50-ml. round-bottomed 'Pyrex' flask with a long neck and fitted with a horizontal break-seal on the lower neck, an upward slanted side arm of 10-mm diameter opposite, and a seal-off constriction on the upper neck. Above the seal-off constriction, the cell was sealed to the stopcock of a vacuum manifold having outlets to the air and to a high vacuum. The cell was flushed before use with nitrogen. The specimen (20 ml.) was introduced into the cell with a hypodermic syringe, frozen with liquid nitrogen and the side arm warmed with an air-heater while the frozen cell was flushed with nitrogen to remove any trace of the specimen that might be contaminating the side arm. The arm was sealed off at atmospheric pressure, the specimen degassed by freezing and pumping, and the frozen cell sealed off at 10^{-6} mm of mercury.

After irradiation, the specimen was frozen with liquid nitrogen, and the non-condensable products (hydrogen, nitrogen and methane) were transferred through the break-seal to a 1 l. calibrated gas-storage bulb by means of a Toepler pump. A 10 ml. portion was analysed quantitatively with a Perkin–Elmer gas chromatograph equipped with a thermistor detector, a 50-ft. Linde molecular sieve column at 30° C, and helium carrier gas.

Table 1. RADIATION YIELDS FOR MONOMETHYLHYDRAZINE WITHOUT AND WITH FREE-RADICAL SCAVENGERS

	Molecules/100 eV			
	$G(H_2)$	$G(N_2)$	$G(CH_4)$	Total

Carbon tetrachloride†	3·3	30·4	25·6	59·3

* Results are average of four experiments.
† Results are average of two experiments.

Table 1 shows radiolytic yields with methyl methacrylate and pentadiene-1,3 as scavengers. Unadulterated monomethylhydrazine produced a large quantity of radiolytic gas. A 20·0 ml. sample (17·5 g) generated 45·5 ml. of non-condensable gas, measured at 25° C and one atmosphere. The molecular composition is 38·7 per cent hydrogen, 33·5 per cent nitrogen and 27·8 per cent methane. The quantity of gas was not altered significantly by the addition of either methyl methacrylate or pentadiene-1,3 as a free-radical scavenger. This suggests that the gas results from a molecular or ionic reaction rather than a diffusion-controlled, free-radical reaction. Undoubtedly, condensable products are also formed, but the formation of the non-condensable products is plausibly accounted for by equation 1 because the gas composition is nearly equimolar, a single molecule of monomethylhydrazine contains the elements of one molecule of hydrogen, nitrogen and methane, and the decomposition is probably uni- or bi-molecular in nature:

$$[CH_3NHNH_2] \rightsquigarrow n\,H_2 + n\,N_2 + n\,CH_4 \quad n = 1 \text{ or } 2 \qquad (1)$$

The presence of carbon tetrachloride affects the radiolytic decomposition of monomethylhydrazine in a surprising way. Table 1 shows that the presence of carbon tetrachloride does not affect $G(H_2)$ significantly, but that it increases $G(N_2)$ and $G(CH_4)$ to values typical of chain reactions. But carbon tetrachloride is known to initiate free-radical chain reactions when irradiated in certain solvents[3,4]. This suggests that two major reactions occur simultaneously. One is the expected molecular (or ionic) reaction in unadulterated monomethylhydrazine which produces the expected equivalent yields of hydrogen, nitrogen and methane. This accounts for the hydrogen gas observed in the radiolysis, but does not account for all the nitrogen and methane gases. The other reaction is a chain reaction initiated by the carbon tetrachloride. It produces no hydrogen gas, but yields nitrogen and methane in amounts which are typical of chain reactions.

Radiolysis of the carbon tetrachloride is a prerequisite for the proposed chain reaction. This proceeds[5,6] according to the equation:

$$CCl_4 \rightsquigarrow Cl\cdot + \cdot CCl_3 \qquad (2)$$

Either of the reactive radicals from carbon tetrachloride will abstract a hydrogen atom from a suitable solvent and generate a new radical to propagate a chain[3,5,7] as suggested, for example, by Hannerz[3].

$$\cdot CCl_3 + R_1R_2CHOH \longrightarrow CHCl_3 + R_1R_2\dot{C}OH \qquad (3)$$

$$R_1R_2\dot{C}OH + CCl_4 \longrightarrow HCl + R_1R_2CO + \cdot CCl_3 \qquad (4)$$

Where the solvent is monomethylhydrazine, reactions (5) and (6) are proposed, taking into account (1) the hydrogen abstraction, (2) the probability of a bimolecular reaction, (3) the requirement (compare Table 1) of producing nitrogen and methane gases in equivalent amounts, (4) the requirement of not producing hydrogen gas, and (5) the necessity of generating a new radical for chain propagation.

$$\cdot Cl + CH_3NHNH_2 \longrightarrow HCl + N_2 + CH_4 + H\cdot \qquad (5)$$

$$\cdot CCl_3 + CH_3NHNH_2 \longrightarrow CHCl_3 + N_2 + CH_4 + H\cdot \qquad (6)$$

$$H\cdot + CCl_4 \longrightarrow HCl + \cdot CCl_3 \qquad (7)$$

These reactions produce two hydrogen radicals between them, and these propagate two identical chains. In the next chain step, a hydrogen radical is scavenged by the carbon tetrachloride according to reaction (7). Thus, the chain reaction in monomethylhydrazine would consist of the alternation of reactions (6) and (7).

The relative reactivity of carbon tetrachloride and monomethylhydrazine with hydrogen radicals is important. It appears that the carbon tetrachloride completely scavenges hydrogen radicals produced by means of reactions (5) and (6), in spite of the high chemical reactivity of monomethylhydrazine. If this were not true, the hydrogen radicals would almost certainly react with monomethylhydrazine molecules to produce hydrogen gas, and the value for $G(H_2)$ would be much greater than the observed value of 3·3 which is wholly accounted for by the molecular or ionic reaction. Reaction (7) is known to occur readily.

The apparent ability of carbon tetrachloride to scavenge hydrogen radicals successfully in monomethylhydrazine increases confidence that methyl methacrylate and pentadiene-1,3 would have scavenged free-radicals in this solvent had the solvent generated primary, radiolytic free-radicals. While these olefines can undergo radiolysis in monomethylhydrazine solution to produce hydrogen and other free-radicals, they act as self-scavengers and cannot, therefore, initiate a chain reaction leading to hydrogen, nitrogen or methane gas.

Approximately 210 molecules each of nitrogen and methane are produced before a chain is terminated. This may be calculated from the G values for monomethylhydrazine-carbon tetrachloride radiolysis in Table 1, a value of 2·6 for $G(\cdot Cl) + G(\cdot CCl_3)$ for pure carbon tetrachloride[5,8], and an estimation that the carbon tetrachloride (5 per cent by volume) absorbs 5 per cent of the total energy input. Chain termination may occur because

the propagating free-radicals combine, although other indeterminate reactions may be responsible.

BIOPHYSICS

Electron Spin Resonance Study of Thermal Effects in Irradiated Deoxyribonucleic Acid

IT has recently been reported that the electron spin resonance spectrum of deoxyribonucleic acid (DNA) irradiated and measured at 77° K is different from that obtained after irradiation at room temperature[1,2]. We have observed that there are three distinct changes in the shape of the spectrum as the sample is warmed from 77° K to 300° K, the final spectrum being the same as that obtained by irradiating at 300° K.

A dry specimen of DNA, extracted from salmon sperm and given to us by the Department of Biophysics, King's College, London, was irradiated at 77° K to a dose of 1 Mrad with cobalt-60 γ-rays in an evacuated 'Spectrosil' sample tube. The derivative spectrum shown in Fig. 1 was recorded at 77° K on an X-band (9 Gc/s) electron spin resonance spectrometer. The sample was brought to various temperatures between 77° K and 300° K for about 5 min before recording the spectrum at 77° K. Changes in the spectrum were irreversible, and were dependent only on the annealing temperature but not on the annealing time at any given temperature. The spectrum after annealing at 100° K is given in Fig. 2 and shows slight differences from Fig. 1, the small amount of structure having disappeared completely. The largest change in the spectrum was observed after annealing at 210° K when a hyperfine spectrum of eight lines was observed. This spectrum is given in Fig. 3. Finally, the central line narrowed at about 260° K to give the spectrum shown in Fig. 4 which is also obtained after irradiation at room temperature. Thus energy transfer occurred at three different temperatures as the specimen was warmed from 77° K to 300° K.

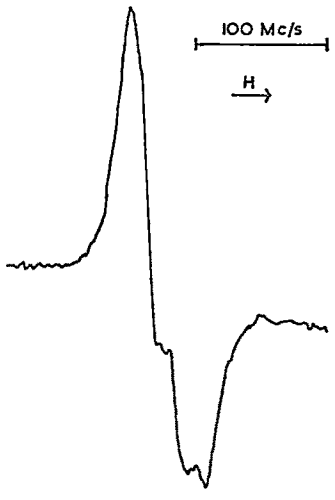

Fig. 1. Derivative spectrum of DNA irradiated and recorded at 77° K

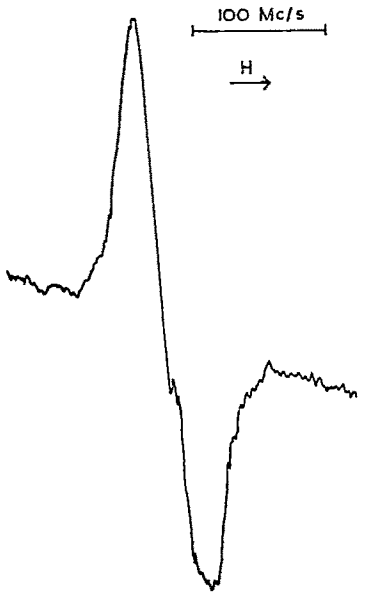

Fig. 2. Derivative spectrum of DNA irradiated at 77° K, annealed for 5 min at 100° K and recorded at 77° K

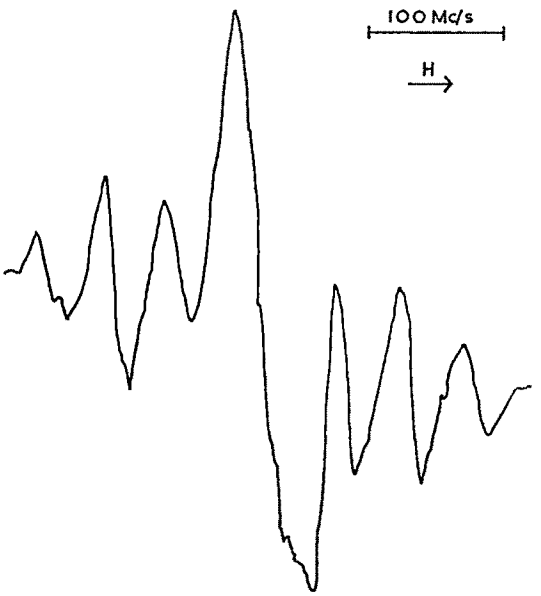

Fig. 3. Derivative spectrum of DNA irradiated at 77° K, annealed for 5 min at 210° K and recorded at 77° K

The single line observed at low temperatures had a peak-to-peak width of 50 Mc/s and the g-value at the centre, measured by comparing its position with that of the α,α-diphenyl β-picryl hydrazyl (DPPH) line, was found to be 2·0036 ± 0·0004. Salovey, Shulman and Walsh[3] have measured the corresponding g-value as 2·0030 ± 0·0005 and the peak-to-peak line width as 72 Mc/s. The total number of radicals decreased by about 15 per cent during the annealing. Alexander, Lett and Ormerod[1] observed a 30 per cent decrease in the number of radicals. However, when allowance is made for different radiation doses and also an estimated error of ± 25 per cent in our experimental measurements, it is doubtful if this difference is significant.

A similar annealing experiment was performed with polycrystalline thymine, thymidine and thymidine monophosphate. After irradiation and measurement at 77° K thymidine gave a spectrum similar to that of the eight-line hyperfine structure observed in DNA irradiated at room temperature. The spectra from thymine and

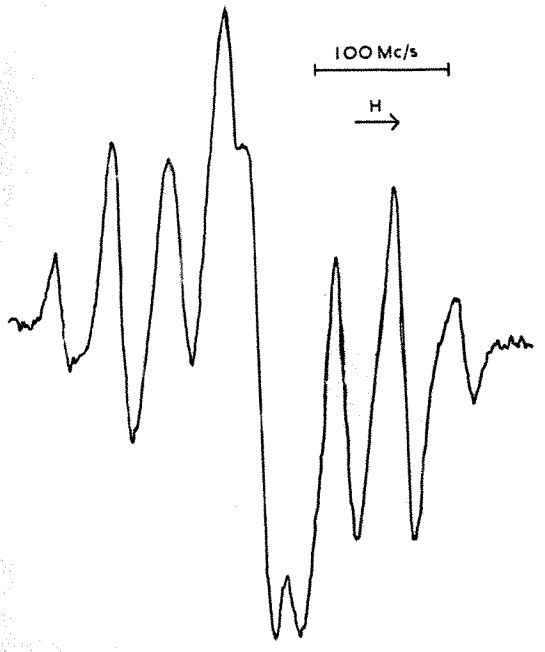

Fig. 4 Derivative spectrum of DNA irradiated at 77° K and recorded at 300° K. A similar spectrum is obtained by recording at 77° K after annealing for 5 min at 300° K

thymidine monophosphate were single lines with a small amount of hyperfine structure and the eight-line spectrum did not appear until the thymine had been annealed to 120° K and the thymidine monophosphate to 160° K. Assuming that the same radical is responsible for the eight-line spectrum in the four compounds, it is clear that the actual temperature of formation of this radical during the annealing process is very dependent on the detailed chemical structure. There is no simple explanation for these differences, such as an increase in temperature of radical formation as the molecular size increases.

Compression of Human Red Cells during Centrifuging

THE question as to whether the mammalian red cell is or is not a 'perfect osmometer' in hypotonic media has been sufficiently discussed[1,2], the perfection of the osmometer being measured in terms of the value of a constant R. The red cells of heparinized blood are usually very good osmometers (R = 0·95–1·0) (refs. 3 and 4), and those of oxalated blood are poor osmometers (R = 0·5–0·8); the value of R, however, depends on the details of the methods used to measure it. Several explanations for the value of R being less than 0·95–1·0 have been suggested, for example, that some of the water in the red cell is bound, that electrolytes escape into hypotonic media, and that crenated or paracrystalline red cells have a real bulk modulus. It has also been suggested that red cells are compressed during high-speed centrifuging[5], the extent of the compression increasing as the quantity of water in the cell increases, and that compression of the cells accounts for values of R less than 0·9–1·0.

In the units used here, and supposing the red cells to be a uniformly packed mass, the equation which expresses the difference in osmotic pressure P between the cells, compressed with a force F, and the fluid surrounding them is:

$$P = 755 \left(\frac{g_1}{v_1 - d} - \frac{g_2}{v_2 + d} \right)$$

where g_1 and g_2 are the electrolytes (in g) in the cells and in the surrounding fluid respectively, where v_1 and v_2 are the volumes of the cells and of the surrounding fluid, and where d is the volume of water transferred at equilibrium from the cells to the surrounding fluid by the force F, which is about 10^6 dynes/mm^2.

First taking normal red cells with a fractional water content of 0·7 and compressing them with the force F, one can obtain a series of values of d_1 and from these a series of values of P_1; then, taking swollen red cells with a fractional water content of 1·4 in a tonicity of 0·5, one can obtain another series of values of d_2 and from these another series of values of P_2. The values d_1 and d_2 for which $P_1 = P_2$ are compared in terms of the volumes of the normal and swollen cells respectively; this gives the compression of the normal and of the swollen cells. The latter is the greater, and from these values R can be calculated.

If $v_1 = v_2$ initially, and if the compression of the normal cells is 0·14, that of the swollen cells is 0·18 and an R-value of 1·0 is reduced to 0·93. If $v_1 = 0{\cdot}5\, v_2$ initially, the compression of the normal cells is 0·1 and that of the swollen cells is 0·19 and an R-value of 1·0 is reduced to 0·89. These reduced values of R, however, are minimum values, because even when $v_1 = v_2$ or $0{\cdot}5\, v_2$ the cells and the supernatant fluid are unlikely to remain homogeneous when the compressing force is applied.

The compressing forces and the compression of the cells at high centrifugal force accordingly exist, but are too small to account for R-values less than about 0·9. Many R-values less than 0·9, however, have been obtained for human red cells of heparinized or defibrinated blood.

BIOCHEMISTRY

Pinguinain : a Simple Method for its Crystallization

RECENTLY we reported[1] the separation of pinguinain, the enzyme present in the fruit of the tropical plant *Bromelia pinguin* L. Using the technique of gel-filtration, we isolated the enzyme from the fruit juice and from crude acetone precipitates which also contained carbohydrates and low molecular weight peptides. Further work on this enzyme led to its crystallization, the procedure for which is the object of this communication.

The starting material used was the juice of the fruits. One hundred millilitres of the juice, which had a *p*H of 3·5–4·0, was neutralized by the addition of 1·0 N sodium hydroxide. At *p*H 7·0–7·2, a dark precipitate was formed and allowed to stand for about 15 min. The

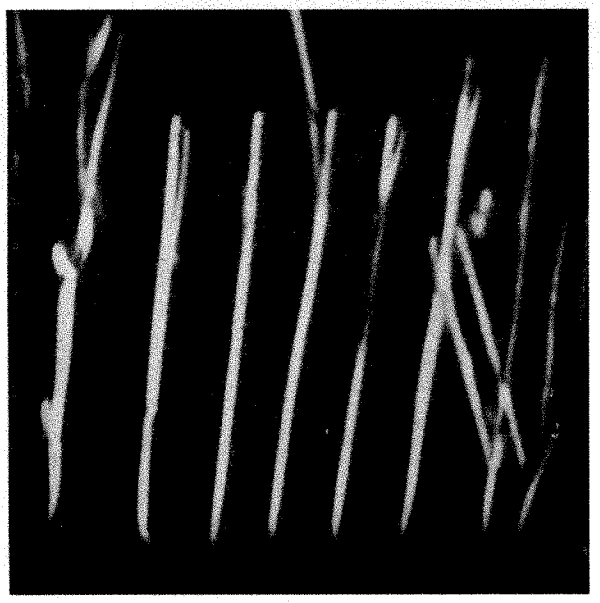

Fig. 1. Pinguinain crystals (average length 150μ) obtained after lyophilization in the presence of 10^{-4} thioglycollic acid. (×400)

suspension was centrifuged for 30 min at 25,000 r.p.m. in a Spinco model *L* preparative ultracentrifuge using an *SW* 25·1 swinging bucket rotor. The clear supernatant was removed and the precipitate, which contained large molecular weight impurities, was discarded. The *p*H of the supernatant was restored to the original. This procedure did not have any deleterious effect on the enzymatic activity of the juice.

The enzyme was isolated from any remaining large molecular weight impurities and peptide material by gel-filtration, using the conditions previously described[1]. Since the isolation of relatively large amounts of enzyme was intended, we prepared cylindrical columns having dimensions of 40 × 5 cm, a gel bed of 600 ml., a void volume of 200 ml. and a rate of flow of 160 ml. per h. Under these conditions 100 ml. of juice was fractionated in 5–6 h. The eluted fractions were collected with the aid of an automatic fraction collector operating on a volume basis (3·0 ml./fraction). Protein contents of the fractions were estimated qualitatively by precipitation with 10 per cent trichloroacetic acid and spectrophotometrically by absorption at 280 mμ. Enzymatic activity was determined as previously described[2]. The fractions containing the protein were pooled. Usually the bulk of the enzyme was found in fractions totalling a volume of 250 ml. The amount of enzyme recovered was 1·5 ± 0·1 g/100 ml. juice, as estimated spectrophotometrically. This was the average yield for ten different preparations made. An $E^{1\%}_{1cm}$ of 22·0 was used for the estimation of protein concentration.

The enzyme solution was exhaustively dialysed against 4 l. of 10^{-4} M thioglycollic acid (Difco Laboratories, Detroit, Michigan). Dialysis was performed for 3 days with three changes of the dialysing solution daily. A portion of the solution was removed for gel-filtration and the remainder was frozen, kept frozen for 2 h and lyophilized. The crystalline material obtained was needle-like (Fig. 1). Crystals had an average length of 150μ, were insoluble in cold 95 per cent ethanol, but dissolved readily in slightly acid or alkaline solutions. They showed least solubility at *p*H 5·5. Crystals could be made to grow by suspending them in 95 per cent methanol and allowing them to stand in the cold (−10° C) for 1 week or longer. Using this procedure, crystals longer than 500μ could be obtained. Kjeldahl digestion indicated that the crystalline material had a nitrogen content of 15·0 per cent. 5 per cent of the total nitrogen appeared to be amide nitrogen. The sulphur content, estimated from methionine and cystine determinations, was 1·1 per cent. Crystals showed a largely diminished enzymatic activity, but this was easily restored with reducing agents containing sulphydryl groups (Table 1). The presence of an SH group compound seems to be necessary for crystallization to occur since lyophilization in the absence of free sulphydryl groups yielded amorphous material.

Table 1. ACTIVATION OF CRYSTALLIZED PINGUINAIN*

Sample No.	Activator	% ^{131}I albumin converted to TCA-soluble radioactivity
1	None	1·0
2	1·0 ml. 0·05 M thioglycollate	43·3
3	2·0 ml. 0·05 M thioglycollate	38·9
4	1·0 ml. 0·05 M L-cysteine, HCl	28·7
5	2·0 ml. 0·05 M L-cysteine, HCl	34·9
6	1·0 ml. 0·05 M sodium cyanide	0·9
7	2·0 ml. 0·05 M sodium cyanide	0·9
8	1·0 ml. 0·05 M ascorbate	0·6
9	1·0 ml. 0·10 M ascorbate	0·6

* Incubation performed in 0·1 M acetate buffer, *p*H 4·0 at 37° C for 20 min. Incubating mixture contained 3·0 mg crystallized pinguinain: 80 mg human serum albumin with 0·4 μc. iodine-131 labelled albumin as tracer; activators as indicated and a total volume of 10 ml.

We consistently noticed that the lyophilization procedure caused a change in the elution pattern of the protein material. The dialysed solution, prior to freezing and lyophilization, appeared homogeneous on gel-filtration in 'Sephadex *G*-100' and '*G*-200', using eluting buffers with *p*H ranging from 4·0 to 7·4. The crystalline material, however, showed two different absorption peaks at 280 mμ (Fig. 2). On 'Sephadex *G*-100' gel-filtration of the crystalline lyophilized material and collection of fractions of the effluent volume (2 ml. each), the faster eluting peak was collected in fractions in which the original prelyophilized enzyme solution appeared when subjected to gel-filtration. This peak contained enzymatic activity proportional to protein concentration and appeared to be homogeneous when further subjected to gel-filtration ('Sephadex *G*-100' or '*G*-200', 0·1 M acetate *p*H 4·6; phosphate saline buffer *p*H 7·3). On treatment of this component with fluorodinitrobenzene and acid hydrolysis of the dinitrophenyl (DNP) protein (5·7 N hydrochloric acid, 18 h), a single ether-insoluble-dinitrophenyl derivative was formed as shown by two-dimensional paper chromatography (butanol–acetic acid–water, 4 : 1 : 1; isobutanol–*n*-butanol–formic acid–water, 2 : 1 : 1 : 3). The second peak appeared in later fractions. The material in the second peak could not be precipitated with trichloroacetic acid, did not show

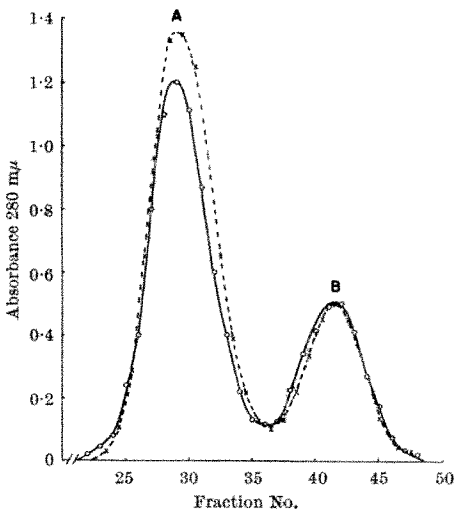

Fig. 2. 'Sephadex *G*-100' (0·01 M acetate, *p*H 4·6) filtration pattern of pinguinain. ——, Lyophilized crystalline material. Note peaks *A* and *B*. The original enzyme solution (prior to crystallization) had an elution pattern identical to peak *A*, but no peak *B*. - - - - -, Pattern for peak *A* of the crystalline preparation after re-dialysis and lyophilization. Notice the reappearance of a peak *B* identical to peak *B* of the original preparation

enzymatic activity and appeared heterogeneous when subjected to paper chromatography.

In our attempt to rule out the possibility that the slower eluting peak might have resulted from concentration of impurities in the original enzyme solution, we performed the following experiment: A solution of crystallized pinguinain was prepared and subjected to gel-filtration in 'Sephadex *G*-100', in a column having dimensions of 40 × 4 cm, using 0·1 M acetate buffer *p*H 4·6 as eluting buffer. The two absorption peaks at 280 mμ appeared. The fractions containing the faster eluting peak were pooled, dialysed as already explained, and lyophilized. Solutions of the crystallized enzyme preparation and of the re-filtered and re-lyophilized material from the faster eluting peak were again subjected to gel-filtration. The two solutions yielded very similar elution patterns (Fig. 2). The slower eluting component reappeared in the crystallized material obtained from the faster eluting peak, thus verifying that the appearance of this component is due to a partial breakdown of some of the protein molecules caused by the crystallization and lyophilization process. Whenever crystallization under these experimental conditions occurs, the optical density ratio between the two components is about 2 : 1.

These results indicate that crystalline pinguinain can be obtained in very high yields using a rather simple method but that its lyophilization causes a partial breakdown of a certain proportion of the molecules. The loss of activity occurring after crystallization is reversible. Crystallization can be accomplished only in the presence of compounds containing free sulphydryl groups. Pinguinain seems to be composed of a single peptide chain, as shown by the production of a single DNP derivative.

Occurrence of 5-Hydroxy-L-tryptophan as a Free Plant Amino-acid

USING labelled amino-acids and chromatographic techniques, it has been shown that 5-hydroxytryptophan is an intermediate in the conversion of tryptophan to the physiologically important base 5-hydroxytryptamine (serotonin) in higher animals[1,2]. The hydroxylation of tryptophan in the 5 position has also been demonstrated in *Chromobacterium violaceum*[3] and in tissue slices of *Citrullus vulgaris* (watermelon)[4].

In these animal, bacterial and plant cells, however, the concentration of 5-hydroxytryptophan is low and confirmation of its presence has rested on indirect evidence rather than on the isolation of the compound itself.

As part of a programme designed to investigate the distribution of 'non-protein' amino-acids in leguminous plants and investigate possible toxic or other physiological effects, which they may produce when eaten by man and higher animals, we have examined the seed of *Griffonia simplicifolia*, a plant of reputed medicinal value, the leaves of which are fed to sheep and goats in West Africa to stimulate reproduction[5]. Ethanolic (50 per cent) extracts of this seed were found to contain high concentrations (estimated at > 1 per cent dry seed weight) of a compound which reacted with ninhydrin, gave a blue-purple colour with Ehrlich's reagent and occupied an unusual position for a plant amino-acid on two-dimensional chromatograms. Tests with α-nitroso-β-naphthol[6] indicated that the compound was a 5-hydroxyindole, and the ultra-violet absorption maxima shown by partially purified aqueous solutions, at acid and alkaline values of *p*H, corresponded with those given in the literature for 5-hydroxytryptophan.

Extracts of the 'unknown' were chromatographed in seven different solvent systems and subjected to high-voltage ionophoresis on paper at four different values of *p*H using authentic samples of 5- and 6-hydroxy-D,L-tryptophan (kindly given by Dr. S. F. Contractor) as 'markers'. In all systems the 'unknown' moved with 5-hydroxytryptophan. In the solvent system previously used to resolve 5-hydroxy-D,L-tryptophan[7], and also in methanol : pyridine : water (20 : 5 : 1 by volume) which was found to separate the optical isomers equally well, the compound from *Griffonia simplicifolia* ran with the slower-moving 5-hydroxy-L-tryptophan. The colour given by the 'unknown' with Ehrlich's reagent was identical both in shade and in rate of development with that given by authentic 5-hydroxytryptophan, and a characteristic change of colour, from purple through green to brown, was observed when 'spots' of the plant amino-acid and of synthetic 5-hydroxytryptophan on paper chromatograms were developed successively with ninhydrin and Ehrlich's reagent.

After isolation and recrystallization the infra-red spectrum of the purified compound was found to be identical with that of synthetic 5-hydroxy-L-tryptophan (supplied by Calbiochem).

The quantitative recovery of this amino-acid from the seed, its distribution, biosynthesis, fate in the plant and the possibility of it being directly or indirectly responsible for the physiological effects attributed to *Griffonia simplicifolia* are at present being investigated.

We thank Miss J. P. O'Donovan for technical assistance, Mr. R. C. Hider for determining the infra-red spectra and Mr. M. A. Apau for help in obtaining plant material.

Acetate and Other Carboxylic Acids as Precursors of Ethylene

THE fungus *Penicillium digitatum*, which is the common green mould of citrus fruit, produces a small amount of ethylene which is of physiological significance to its host. The mechanism of ethylene synthesis by the fungus and other plant tissues has been explored in several laboratories by supplying postulated precursors specifically labelled with carbon-14 or tritium. Burg[1] reviewed this work in 1962 and concluded that ethylene is "synthesized fairly directly from sugar, but the steps between glucose and the final product have completely evaded detection". Wang *et al.*[2] have fed specifically labelled sugars and acids to *Penicillium digitatum* and concluded that an "intimate

relationship between ethylene and the tricarboxylic acid cycle is indicated". Burg and Burg[3] provided apple slices with a number of specifically labelled compounds and stated that it is "presumptuous to conclude [that] the relationship [between Krebs cycle acids and ethylene] is very direct".

This communication reports the production of ethylene of high specific activity in relation to the carbon dioxide evolved by *Penicillium digitatum* when acetate-2-^{14}C was fed and re-affirms by an improved method that pyruvate-3-^{14}C yields ethylene of higher specific activity than does pyruvate labelled in the 1 or 2 positions[4]. An improved method for the collection and counting of the carbon dioxide and ethylene is described which is less tedious and does not require shaking or handling of the fungal mats. Disturbing the mats lowers the ethylene production.

Cultures of *Penicillium digitatum NRRL* 1202 isolate were grown in stationary Fernbach flasks at 20° C on citrate medium as described by Gibson[4]. When high ethylene production was observed ($\geqslant$40 μl./h/culture), the medium on which the culture was growing was sucked off and 100 ml. of fresh citrate medium was added. About 25 μc. of ^{14}C-labelled compound was added and ethylene-free air was passed over the culture at a rate of 60 ml./min. The effluent of the culture was dried and passed through a Beckman infra-red gas analyser to determine the total carbon dioxide and then to the 250-ml. ionization chamber of a Cary model 31 electrometer to determine the total radioactivity in the gas stream. Carbon dioxide in the effluent of the electrometer chamber was removed by two 'Ascarite' tubes in series, and the last traces of water and most of the volatile organic compounds by a glass trap held in a dry ice bath. Ethylene was then adsorbed on 0·25 g of silica gel (Davidson 40–60-mesh refrigeration grade *PA*-100) contained in a copper U-tube of 3/16 in. diameter held in a dry ice bath as suggested by Pratt[5]. After adsorbing ethylene for 15–60 min, silica gel in the copper U-tube was connected in the helium input line of a thermal conductivity gas chromatograph. When the tube was transferred to a 40° C bath, ethylene was released immediately from the silica gel and was resolved by a 0·125 × 18-in. column of alumina (Alcoa *H*-151, 60–80 mesh). The ethylene peak was trapped in a 250-ml. Cary flow-type ionization chamber for determination of radioactivity. That the radioactivity was in ethylene was checked periodically by absorption and release from mercuric perchlorate[6] and recounting.

Table 1. SPECIFIC ACTIVITY OF CARBON DIOXIDE AND ETHYLENE AT HOURLY INTERVALS AFTER ADDING SPECIFICALLY LABELLED COMPOUNDS TO CULTURES OF *Penicillium digitatum*

Compound	Gas	Disintegrations per min/μ mole: Hours 1	2	3	4	5	6
Acetate 1-^{14}C	C_2H_4	nil	nil	nil	15		
	CO_2	4,290	4,080	2,950	1,950		
Acetate 2-^{14}C	C_2H_4	3,520	8,880	7,120	6,180	4,150	
	CO_2	1,470	2,410	2,200	1,830	1,650	
Pyruvate 2-^{14}C	C_2H_4	30	40	150	140	300	125
	CO_2	630	1,000	1,100	1,060	1,070	990
Pyruvate 3-^{14}C	C_2H_4	1,110	4,440			4,130	3,840
	CO_2	100	460			740	700
Malate 3-^{14}C	C_2H_4	880	1,950	1,900	2,830	3,110	
	CO_2	1,310	1,560	1,670	1,600	1,600	

The purity and activity of the isotopes used were checked by paper chromatography and scintillation counting.

The specific activity of ethylene and respiratory carbon dioxide at various times after the addition of specifically labelled acids is shown in Table 1. When acetate-1-^{14}C was used, the specific activity of carbon dioxide was very high during the first hour and decreased rapidly thereafter. There was no activity in ethylene during the first 3 h and only a trace during the fourth hour. On the other hand, when acetate-2-^{14}C was supplied, the specific activity in ethylene was twice that of carbon dioxide for the first 5 h and the pools leading to both carbon dioxide and ethylene were maximally labelled during the second hour.

When pyruvate-2-^{14}C was fed, the specific activity in ethylene was at first less than one-tenth that of carbon dioxide, while pyruvate-3-^{14}C yielded ethylene with a specific activity of about ten times that of carbon dioxide for the first 2 h. Carbon dioxide from pyruvate-3-^{14}C became labelled more slowly than the 2 position. This was to be expected if pyruvate was oxidized through the TCA cycle.

Carbon dioxide from malate-3-^{14}C was labelled at about the same rate as was carbon dioxide from pyruvate-2-^{14}C. This finding is consistent with oxidation through the TCA cycle. Ethylene was labelled more slowly, the ratio of specific activity in ethylene to that in carbon dioxide increasing from 0·6 to 1·9 over 5 h. This suggests that some malate may be converted to pyruvate and then to ethylene by a path leading away from the TCA cycle.

If our interpretation of the data on malate is correct, only one carbon, C2 of acetate or C3 of pyruvate, is incorporated extensively in the ethylene molecule. The rates at which ethylene becomes labelled suggest that the path to ethylene synthesis is not through steps of the TCA cycle, but rather that TCA cycle intermediates go to pyruvate or glycolate and acetate where C2 or C3 combines with another molecule which in turn leads to ethylene synthesis.

These observations of ethylene production by *Penicillium digitatum* are in marked contrast to those of Burg and Burg[3], who showed that ethylene initially synthesized by apple tissue became labelled equally well from acetate labelled in either 1 or 2 positions and pyruvate in the 2 or 3 positions. The specific activity in ethylene was much less than that of carbon dioxide. It is probable that ethylene is formed by a different mechanism in fruit.

Induction of Tyrosine Transaminase in Rat Liver by Actidione

ACTIDIONE (*cyclo*heximide) inhibits protein synthesis in yeasts, certain protozoa and mammalian cell lines[1–3]. It is a toxic compound for some mammalian species, for example, rats; however, in these cases, hydrocortisone acts as an antidote against such poisoning[4]. We recently reported[5] that actidione in rats stimulates the adrenal cortex by way of the anterior pituitary. The stress reaction protected rats against actidione while hypophysectomy or adrenalectomy made them more sensitive to actidione poisoning[5]. Furthermore, mice (which are normally highly resistant to actidione poisoning[4,5]) became sensitive to actidione after adrenalectomy[5].

The effect of actidione may thus be profoundly modified by hormonal factors. In the rat, repeated injection of actidione (0·2 mg for five consecutive days) brings about a stress-induced increase of adrenal protein and RNA; but the DNA increase, which occurs after repeated administrations of ACTH and accompanies a large increase of total RNA[6], is blocked by actidione[5]. An accumulation of RNA in the microsomal fraction of rat liver has also been observed[5].

In unicellular organisms, inhibition of protein synthesis can be produced by a smaller dose of actidione than is needed for the inhibition of DNA synthesis[7]. The synthesis of an inducible enzyme, such as β-galactosidase, was reported to be inhibited by actidione even in bacteria where actidione does not inhibit the growth[8]. It was of interest, therefore, to investigate whether or not actidione inhibits the induction of enzymes such as tyrosine-α-ketoglutarate transaminase (TT) and tryptophan pyrrolase (TPO) in the rat liver: this was especially so because both these enzymes are known to be inducible by hydrocortisone[9–11].

Male Sprague–Dawley albino rats (average body-weight 200 g) were used for these experiments. TT and TPO were assayed by Knox's methods[12,13]. Actidione injected intraperitoneally to the extent of 1 mg per kg body-weight inhibited the induction of TPO, assayed 4 h after administration of substrate (200 mg) or by hydrocortisone (10 mg). The addition of microsomes or of haematin to assayed mixtures did not affect these results. In contrast, actidione did not abolish the induction of TT by hydrocortisone. Furthermore, in the absence of hydrocortisone, actidione increased the level after 4 h. A similar, although smaller, effect also occurred in hypophysectomized rats. The effect was, therefore, not caused by the release of corticosteroids by way of the anterior pituitary, but suggested a possible direct induction of TT by actidione. This conclusion was warranted by further experiments with adrenalectomized rats. An increase in the level of liver TT of some 250–300 per cent was observed 4 h after administration of actidione. The same results were obtained using a modified Briggs reaction[14] for assay of tyrosine transaminase. The induction of TT by actidione increased linearly with time for the period of 2·5 h and reached a maximum after 4 h. Puromycin hydrochloride (Nutritional Biochemicals) completely prevented the induction of TT. These results are summarized in Table 1.

Table 1. EFFECT OF ACTIDIONE (*Cyclo*HEXIMIDE) ON TYROSINE-α-KETOGLUTARATE TRANSAMINASE ACTIVITY IN RAT LIVER

Exp. No.	Animal No.	Treatment	Enzymatic activity after 4 h	Change (%)
(1) Intact	1	Saline	54	—
	2	Hydrocortisone	204	+277
	3	Hydrocortisone + actidione	388	+618
	4	Actidione	358	+562
	5	Actidione	418	+674
(2) Hypophysectomized	6	Saline	83	—
	7	Hydrocortisone	277	+233
	8	Actidione	275	+231
	9	Actidione	286	+244
	10	Actidione	280	+237
(3) Adrenalectomized	11	Saline	50	—
	12	Actidione	238	+370
	13	Actidione	212	+320
	14	Actidione	220	+340
	15	Actidione + puromycin	47	—
	16	Actidione + puromycin	57	—

Enzymatic activity is expressed in μmoles of *p*-hydroxyphenylpyruvate formed/g liver/h at 37° C, 4 h after treatment. 10 mg hydrocortisone sodium succinate (*o*) injected intraperitoneally. Actidione (Upjohn, Kalamazoo, Michigan) 1 mg/kg body-weight. 15 mg puromycin hydrochloride (Nutritional Biochemicals) was given at −1 and 0 h, and 10 mg in 1 h from the administration of actidione.

Assay of TT performed with 0·3 ml. supernatant (15 min at 30,000*g*) of 10 per cent (in saline) homogenate of liver. The reaction mixture with all supplements (see ref. 13) incubated for 15 min at 37° C. The reaction stopped with 1 c.c. 30 per cent TCA. Spectrophotometric readings made at 310 mμ.

These findings demonstrate that an inhibitor of protein synthesis, such as actidione, may also act as an inducer for the synthesis of the enzyme tyrosine transaminase, perhaps by stimulating the action of hydrocortisone. This 'pseudohormonal' action of actidione may explain the toxicity of actidione in certain mammalian species and also the fact that hydrocortisone may act as an antidote in actidione poisoning. It does not explain why a similar effect of 'pseudohormonal' induction is not observed in the case of TPO, but only the inhibition of enzyme induction. One possible explanation may be that the targets for induction of TPO and TT have a great affinity for both hydrocortisone and actidione, but a different degree of specificity required to bring about the synthesis of each of these enzymes; in the case of TT, hydrocortisone may be replaced by actidione for the induction of the enzyme, whereas for TPO the enzyme can be induced only by hydrocortisone.

2-Acetamidofluorene and 3-Methylcholanthrene: Differences in Binding to Rat Liver Deoxyribonucleic Acid *in vivo*

THE relationship between mutagenesis and carcinogenesis is still a matter of controversy[1]. The problem is particularly unresolved with respect to liver cancer induced by chemicals. Although hepato-carcinogenic nitrosamines are known to alkylate liver DNA *in vivo*[2], similar binding to liver DNA *in vivo* has not been reported for the two other most intensively studied groups of liver carcinogens, namely, the fluorenamines and the aminoazo dyes. Although, at present, one cannot make definitive interpretations of the functional significance (with respect either to DNA replication or to DNA transcription) of the binding of a carcinogen to the DNA in a liver cell, studies are needed which correlate carcinogenicity of various compounds with their binding *in vivo* to gene material. This report describes the binding of the strongly hepato-carcinogenic agent 2-acetamidofluorene[3] (*N*-2-fluorenylacetamide, AAF) to rat liver DNA after intraperitoneal injection. In a parallel *in vivo* experiment the aromatic hydrocarbon, 3 (or 20) -methylcholanthrene (MC), which is not carcinogonic for rat liver[4] (although it does cause significant alterations in both RNA[5] and protein[6] synthesis in this organ), was found not to bind to rat liver DNA.

Fischer male rats, 8–10 weeks old, weighing 140–180 g, were injected intraperitoneally with either 6 mg of AAF-9-^{14}C (synthesized by Drs. E. K. and J. H. Weisburger[3], radiopurity greater than 98 per cent by paper chromatography in *cyclo*hexane–*t*-butanol–acetic acid–water, 16 : 4 : 2 : 1) or 3 mg of MC-^{3}H, generally labelled (Nuclear Chicago, Des Plaines, Ill., radiopurity greater than 95 per cent by paper chromatography in methanol–ether–water, 4 : 4 : 1). The rats were killed at the times

indicated in Table 1. In each experiment 3 g of liver from each of two identically treated rats were pooled and highly purified nuclei were isolated as described previously[7]. The nuclei were suspended evenly in approximately 8 ml. of 0·32 M sucrose, 0·002 M magnesium chloride, 0·001 M potassium phosphate, *p*H 6·8, and lysed by the addition of 42 ml. of 6·5 M caesium chloride, containing 0·005 M trisodium EDTA. Gentle homogenization with the loose pestle of a Dounce homogenizer was necessary to assure complete lysis of nuclei. The final density of the lysate was 1·66. The DNA was separated from the other nuclear constituents by centrifuging 9-ml. portions of the nuclear lysate for 64 h at 45,000 r.p.m. and 20° C in an angle rotor[8] (International rotor No. 965, *T*-60 ultracentrifuge). Under these conditions, the DNA forms a sharp band just below the middle of the tube at its equilibrium density of 1·70 (ref. 9); RNA is sedimented to the bottom of the tube and protein migrates to the top. Fractions of 0·5 ml. were collected by punching a hole in the bottom of the tube with a 27 gauge needle, and absorbancy at 260 mμ was measured on 0·1 ml. aliquots after dilution to 3·0 ml. (Fig. 1). Radioactivity assays were made on 0·2 ml. aliquots from all fractions (Fig. 1) by adding 200 μg carrier DNA, precipitating with ice-cold 10 per cent trichloroacetic acid (TCA), washing with ice-cold methanol, and dissolving the precipitate in 1 ml. of hyamine hydroxide before counting in a liquid scintillation counter. Caesium chloride densities were determined by refractive index measurements[10], after correcting for the presence of sucrose in the nuclear lysates.

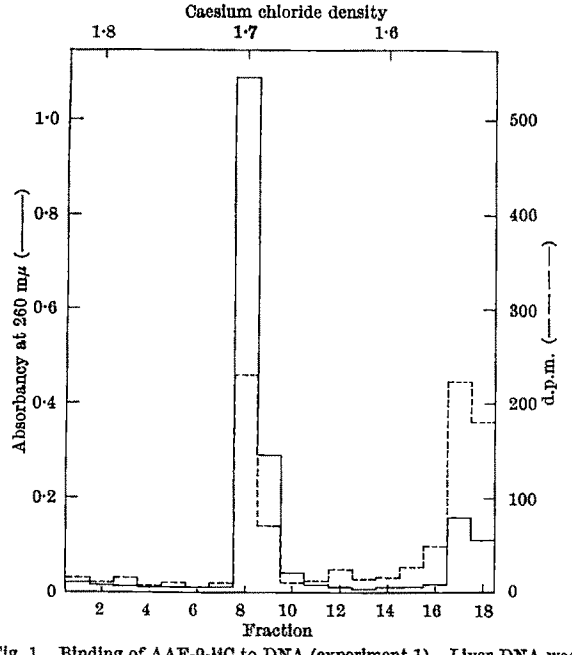

Fig. 1 Binding of AAF-9-^{14}C to DNA (experiment 1). Liver DNA was banded by density equilibrium centrifugation in caesium chloride. Fractions of 0 5 ml. were collected Absorbancy figures are those obtained after 1 : 30 dilution of aliquots (1 cm light path). The plotted radioactivity figures are those obtained on separate 0·2-ml. aliquots

The results in Table 1 and Fig. 1 show that AAF or a metabolite thereof binds to rat liver DNA, while no binding of MC to DNA was detectable. It is of particular interest that binding of AAF to DNA occurs within 2 h of administration of the compound (experiment 1). Table 1 also shows the total radioactivity in the entire nuclear lysates after precipitation with ice-cold 10 per cent TCA and washing the precipitate with cold methanol. In experiments 1, 2 and 3, about 50 per cent of this radioactivity was resistant to two extractions with hot 10 per cent TCA (90°, 15 min each time) and two subsequent extractions with methanol at room temperature. In experiment 4, in contrast, essentially none of the MC radioactivity in the nuclear lysate (precipitated by cold TCA) was extracted by treatment with hot TCA and methanol.

Table 1. BINDING OF 2-ACETAMIDOFLUORENE AND 3-METHYLCHOLANTHRENE TO RAT LIVER DNA AFTER SINGLE INTRAPERITONEAL INJECTION

Experiment	Labelled compound	Duration of isotope treatment	Total d.p.m. in entire initial homogenate	Total d.p.m. in entire nuclear lysate precipitated by cold TCA	μMoles of compound bound to DNA per mole DNA-phosphorus
(1)	AAF, 220 μc /rat	2 h	$36·6 \times 10^6$	$7·1 \times 10^4$	14
(2)	AAF, 220 μc./rat	23 h	$7·8 \times 10^6$	$12·5 \times 10^4$	17
(3)*	AAF, 220 μc./rat	23 h	$2·7 \times 10^6$	$1·8 \times 10^4$	4·8
(4)	MC, 450 μc./rat	23 h	$10·2 \times 10^6$	$2·3 \times 10^4$	<0·08 (Lowest limit of detection)

AAF-9-^{14}C, specific activity 8 mc /mmole, was administered in 0·2 ml. of dimethyl sulphoxide. MC-^{3}H, specific activity 40 mc./mmole, was administered in 0·5 ml of dimethyl sulphoxide. For each experiment 2 rats were used and their livers pooled at the time of killing.

* In experiment 3 the rats were pre-fed for 3 weeks with 0·03 per cent AAF in a semi-synthetic diet before injection and then placed on standard ration after injection; in experiments 1, 2 and 4 the rats were fed *ad lib.* on standard commercial laboratory ration.

In all experiments the banding density of the DNA indicated that the protein remaining bound to the DNA during density equilibrium centrifugation was less than 3 per cent. Furthermore, the low buoyant density of proteins would not allow AAF, bound only to protein, to form a radioactivity peak overlapping the DNA band. At this point the nature of the binding of AAF to DNA is unknown. According to Marroquin and Farber[11], who have previously reported binding of AAF to liver RNA *in vivo*, the possibility that nucleotides might become labelled from carbon dioxide derived from AAF-9-^{14}C is quite unlikely. The level of binding of AAF to DNA is approximately of the same order of magnitude as has been found for binding of single doses of carcinogenic aromatic hydrocarbons to mouse skin DNA[12] or for binding of physiologically significant doses of actinomycin *D* to rat liver DNA[13].

It is of interest that MC, which is not carcinogenic for rat liver, did not bind to rat liver DNA *in vivo*. This is in direct contrast to its behaviour in mouse skin, for which MC has been found to be both a potent carcinogen[4] and a firm binding agent to DNA *in vivo*[12]. It is conceivable that species and organ differences in the carcinogenicity of MC may be related to the extent of DNA binding, which in turn may be related to differential metabolism of this hydrocarbon. Further investigations on the binding of liver carcinogens and their non-carcinogenic analogues to DNA are in progress and will be published elsewhere in greater detail.

We thank Drs. E. K. and J. H. Weisburger for a generous gift of AAF-^{14}C and Messrs. J. M. Smith and W. R. Henderson for valuable technical assistance.

Stimulation of Fermentation in Yeasts by Acetoin and Oxygen

In Warburg experiments with 'resting' cells, most yeasts show a Pasteur effect, that is, fermentation of glucose is inhibited under aerobic conditions. This effect is generally regarded as an inhibition of fermentation by respiration, for example, as a result of a lack of inorganic phosphate (P_i) or adenosine diphosphate (ADP)[1,2].

However, in yeasts belonging to the genus *Brettanomyces*, fermentation of glucose is inhibited under anaerobic conditions[3,4]. This 'negative Pasteur effect', as it was named by Custers[3], is attributed to an initial shortage of nicotinamide-adenine dinucleotide (NAD)[5], brought about by the activity of redox systems in the cell after the addition of glucose[6]. It can be abolished by various carbonyl compounds, reoxidizing $NADH_2$ enzymatically, and by oxygen, reoxidizing $NADH_2$ by way of the respiratory chain to NAD, which then takes part in the fermentation[5]. Hence the term 'negative Pasteur effect' is less appropriate and may even be confusing, since it suggests a close relationship with the Pasteur effect. For this reason, the term 'Custers effect' is here proposed for this inhibition of alcoholic fermentation under anaerobic conditions.

The question arose whether an inhibition under aerobic conditions and an inhibition under anaerobic conditions may occur in one and the same yeast; in other words, whether a Pasteur effect may be masked by a Custers effect, or vice versa.

In order to elucidate this point, further experiments were performed on the effects of a carbonyl compound (acetoin) and oxygen in low concentrations on fermentation in yeasts, using the method given in detail by Wikén *et al.*[4].

With *Brettanomyces* spp., addition of acetoin (10^{-3} M) or of small amounts of oxygen (such as 0·1 per cent of the gas phase) to the anaerobic yeast suspensions stimulates fermentation of glucose to rates even larger than those in air (Fig. 1, Table 1). Apparently, at certain low oxygen tensions, the anaerobic inhibition of fermentation is overcome by oxidation of $NADH_2$ by way of the respiratory chain, whereas the depressing effect of respiration on fermentation, known as the Pasteur effect, does not yet manifest itself to the full extent. It is concluded that in *Brettanomyces* spp. the Pasteur effect is obscured by the Custers effect, but may become evident after the anaerobic inhibition of fermentation is abolished by addition of acetoin or oxygen in low concentrations.

Furthermore, acetoin enhances anaerobic fermentation in many yeasts showing a Pasteur effect; low concentrations of oxygen may have a similar effect (Fig. 2, Table 2). It is concluded that in these yeasts a partial

Table 1. FERMENTATION IN *Brettanomyces* SPECIES

Brettanomyces schanderlii	2796	I	44	*A*	364	429	2–6	653	561	0·09

The yeasts were grown in shake cultures at 30° C in a synthetic liquid medium (I) or in yeast water with 2 per cent glucose (III). After being collected and washed, the cells were suspended in distilled water (*A*) or in 0·05 M potassium dihydrogen orthophosphate, pH 4·5 (*B*). Acetoin was added together with glucose from the side arm of the Warburg flasks at $t=0$. The glucose concentration in the Warburg vessels was 0·1 M. To obtain the desired oxygen concentrations, measured volumes of air were admitted shortly before $t=0$ to anaerobic Warburg vessels. The manometric experiments were performed at 30° C. The values for the aerobic fermentation were calculated without correction for respiration (ref. 4).

inhibition of fermentation under anaerobic conditions is masked by the Pasteur effect.

As may be seen from Tables 1 and 2, the occurrence of a Pasteur effect and a Custers effect, respectively, is not restricted to yeasts grown in a particular medium or suspended in a particular system. As might be expected, acetoin has little effect on aerobic fermentation. As regards the effect of acetoin on anaerobic fermentation, it must be emphasized that not all yeasts will necessarily have a dehydrogenase system for the oxidation of $NADH_2$ by acetoin. The oxygen concentrations, chosen arbitrarily, will not necessarily be the optimal ones for obtaining a maximum fermentation rate, and this is shown in Fig. 2.

In summary, it is concluded that in one and the same yeast, fermentation may be inhibited: (1) by higher oxygen tensions leading to a shortage of, for example, P_i or ADP as a consequence of respiratory chain phosphorylation; (2) by anaerobic conditions leading to a shortage of NAD.

Depending on the ratio between these two inhibitions, a Pasteur effect or a Custers effect is observed as a net result. An optimal oxygen concentration may be found at which the rate of fermentation is maximal.

Induction of Enzyme Activity in Pea Tissues by Animal Hormones and by Puromycin

IT was shown previously[1] that the ability of pea stem segments to synthesize benzoylaspartate is greatly increased by pretreatment with indolyl-3-acetic acid (IAA) and that this inducing effect is suppressed by actinomycin *D* and by puromycin, inhibitors of ribonucleic acid[2] (RNA) and protein synthesis[3], respectively. In extending this work it has been found that certain animal hormones, and more surprisingly puromycin, also act as inducers of the aspartate conjugation system.

Segments of pea epicotyls excised from the apex of the third internode were treated for 16 h in the appropriate buffered medium and then transferred for 2 h to 10 mg/l. of benzoic acid (carboxyl-^{14}C). The segments were extracted in 80 per cent ethanol containing sodium carbonate and the amount of benzoylaspartate formed was estimated as described previously[1].

The data of Table 1 show that thyroxine, hydrocortisone and testosterone elicit a three- to five-fold increase in benzoylaspartate production and that their inducing activity, like that of IAA, is completely suppressed by the presence of 5 mg/l. of actinomycin *D* during pretreatment. It has already been established[1] that this level of actinomycin strongly inhibits RNA synthesis in pea stem segments. In another experiment, with varying concentrations of thyroxine (Fig. 1), a maximum response was obtained at 100 mg/l. (seven-fold induction); inclusion of actinomycin abolished induction at all thyroxine concentrations tested. The extent of induced conjugate formation in response to the animal hormones is somewhat variable, and in particular a clear optimal concentration as in Fig. 1 is often not obtained. For thyroxine and testosterone at least, this is probably because they are present in fine suspension, being initially dissolved in a small quantity of ethanol (insufficient to affect growth or conjugation), which is then dispersed in the aqueous incubation medium. Thus the effective external concentration can be expected to vary with the degree of dispersion from sample to sample.

Table 1. EFFECT OF ACTINOMYCIN *D* DURING PRETREATMENT ON THE INDUCTION OF BENZOYLASPARTATE FORMATION BY VARIOUS HORMONES

Pretreatment	Benzoylaspartate formed μg	Benzoylaspartate formed Per cent conversion
Buffer	1·2	5·7
AM	0·0	0 0
L-Thyroxine 200 mg/l.	6·8	25·9
L-Thyroxine 200 mg/l. + AM	0·0	0·0
Hydrocortisone 200 mg/l.	3·3	15·9
Hydrocortisone 200 mg/l. + AM	0·0	0·0
Testosterone propionate 200 mg/l.	3·9	21·4
Testosterone propionate 200 mg/l. + AM	0·0	0·0
IAA 50 mg/l.	6·7	51·5
IAA 50 mg/l. + AM	0 0	0 0

Incubation conditions were as described in the text. Actinomycin *D* (AM) was used at 5 mg/l.

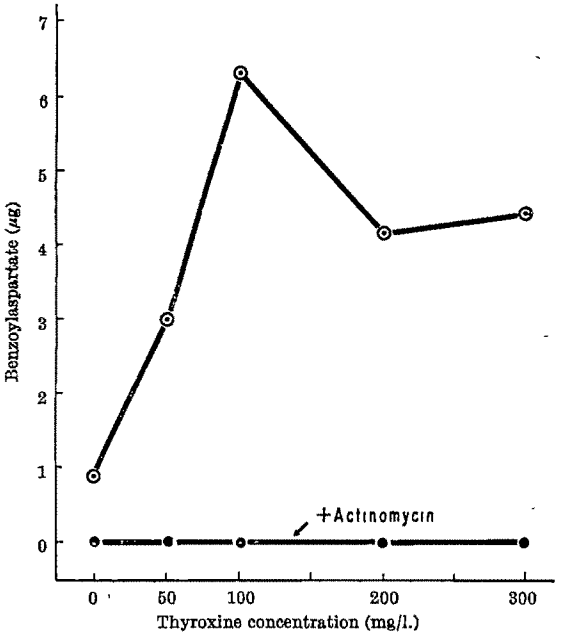

Fig. 1. The effect of pretreating pea stem segments for 16 h in various concentrations of thyroxine with (●) or without (○) 5 mg/l. of actinomycin *D* on the amount of benzoylaspartate formed after transference for 2 h to labelled benzoic acid (10 mg/l.)

When the action of puromycin on the hormonal induction is investigated, certain apparently anomalous results appear. Puromycin effectively represses benzoylaspartate synthesis induced by testosterone, hydrocortisone and by IAA (Table 2), but fails to reverse the effect of thyroxine. Moreover, with puromycin alone during pretreatment, in the absence of any hormone, conjugate formation is increased three-fold. Data on the fresh weight increase of the tissues during pretreatment (Table 2) show that in the cases where puromycin is effective in suppressing hormonal induction, growth is severely retarded, whereas the treatments of puromycin alone or in combination with thyroxine are relatively non-inhibitory. It would appear as if applications of hydrocortisone, testosterone and indolyl-3-acetic acid in some way increase tissue susceptibility to puromycin, one manifestation being that synthesis of the conjugation enzyme becomes puromycin-sensitive. Such a difference is not, however, reflected in the overall rates of protein synthesis (Table 3): puromycin, whether in combination with thyroxine or with testosterone, inhibits leucine incorporation to about the same extent (85 per cent and 80 per cent, respectively). The hormones themselves reduce leucine incorporation, an effect previously noted for IAA under similar conditions[1]. This action is not incompatible with induction of an enzyme representing a small proportion of the total protein synthesized.

Table 2. Effect of Puromycin during Pretreatment on the Induction of Benzoylaspartate Formation by Various Hormones

Pretreatment	Benzoylaspartate formed (μg)	Gain in fresh wt. (%)
Buffer	1·4	24·2
PM	4·3	14·6
PM + actinomycin 5 mg/l.	0·0	9·5
L-Thyroxine 100 mg/l.	4·9	24·1
L-Thyroxine 100 mg/l. + PM	5·6	16·9
Testosterone propionate 100 mg/l.	3·8	21·8
Testosterone propionate 100 mg/l. + PM	1·1	2·4
Hydrocortisone 100 mg/l.	7·6	6·7
Hydrocortisone 100 mg/l. + PM	0·4	−3·6
IAA 50 mg/l.	9·2	49·2
IAA 50 mg/l. + PM	0·8	−0·6

Incubation conditions were as described in the text. Fresh-weight gains were measured after the 16-h pretreatment period. Puromycin (PM) was used at 10^{-3} M.

Table 3. Effects of Thyroxine, Hydrocortisone and Puromycin on the Incorporation of Leucine-^{14}C into Protein

Treatment (2 h+3 h)	Specific activity of protein (c.p.m./mg)
Buffer	867
Puromycin	290
L-Thyroxine 100 mg/l.	472
L-Thyroxine 100 mg/l. + PM	131
Hydrocortisone 100 mg/l.	512
Hydrocortisone 100 mg/l. + PM	178

Pea stem segments were treated for 2 h in the appropriate medium prior to the addition of DL-leucine-1-^{14}C ($2·6 \times 10^{-5}$ M) for a further 3 h. All media contained 15 mg/l. of benzylpenicillin. Incorporation was determined in a manner similar to that of Osborne (ref. 4). Puromycin was used at 10^{-3} M.

The anomalous puromycin effect may be compared with similar reports of actinomycin-induced increases in enzyme activity[5] and in ferritin protein synthesis[6]. Increased alkaline phosphatase activity in response to both actinomycin and puromycin has been noted[7]. At this stage it is scarcely worth speculating on the interpretation of the puromycin-induced increase in benzoylaspartate synthesis, except to note that this action of puromycin is actinomycin-sensitive (Table 2) and that actinomycin alone has no such effect (Table 1 and Fig. 1). Thus activation of pre-existing enzyme by puromycin is not a likely explanation.

Carlisle *et al.*[8] reported that locust extracts containing the moulting hormone ecdysone showed activity in a dwarf pea gibberellin bioassay, while gibberellic acid injected into locust larvae mimicked the action of ecdysone on moulting. The present report serves as a further indication that some animal and plant hormones may, superficially at least, have certain properties in common.

I thank M. W. H. van Ysselstein for technical assistance, and Merck, Sharp and Dohme Research Laboratories, Rahway, N.J., for a generous gift of actinomycin *D*.

Proposed Catalytic Role for Histidine in Pyridine Nucleotide-linked Alcohol Dehydrogenases

The appearance of histidine close to essential thiol groups in a number of alcohol dehydrogenases[1], coupled with various inactivation[2] and inhibition[3] experiments, suggests the possibility of histidine involvement in the catalytic step of certain pyridine nucleotide-linked enzymatic oxidation-reduction processes. The purpose of this communication is to propose a simple concerted mechanism which allows histidine to fulfil such a role by both substrate and coenzyme activation.

Assume that in the ternary complex of enzyme–coenzyme-substrate, the alcohol or carbonyl group of the substrate is located in sandwich fashion between the imidazole ring of histidine and the nicotinamide ring of the pyridine nucleotide, as shown in Fig. 1 (I) and (II). The two rings are positioned so that the α-nitrogen of imidazole and the pyridine nitrogen are close to each other and may be slightly tilted to bring the two nitrogens closer together. Oxidation and reduction are viewed as proceeding by a concerted and virtually cyclic mechanism (I⇄II) which would allow a low-energy common transition state, intermediate in structure between (I) and (II). The direction of electron movement is indicated by the arrows.

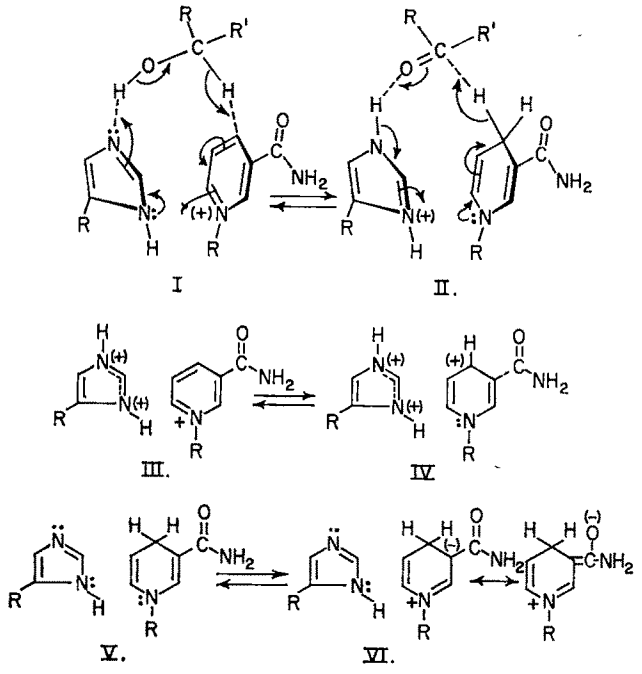

Fig. 1. Proposed participation of enzyme histidine in enzymatic oxidation-reduction processes

Catalytic aid with respect to the substrate, which has been previously suggested by Winer and Schwert[3] for lactic dehydrogenase, may be understood by visualizing the reaction in discrete steps even though the process is considered as concerted and the relative timing of proton and hydride transfer cannot be defined. In the oxidative direction proton transfer from the alcohol to the imidazole nitrogen would generate partial negative charge on oxygen and facilitate the transfer of hydride ion to the pyridinium ring. In the reductive direction, protonation of the carbonyl group by imidazolium would generate partial carbonium ion character on the carbonyl carbon, thereby facilitating the transfer of hydride ion from the reduced pyridine nucleotide. Alternately, assuming hydride transfer as the ultimate step in the oxidative direction and microscopic reversibility, reaction in the reductive direction would require initiation by hydride transfer with stabilization of the incipient negative charge on oxygen by the imidazolium proton.

A second catalytic function based on charge localization in the two nitrogen-containing rings may lead to coenzyme activation. (I) and (II) represent the mutually stabilized charge situation with respect to the two opposing nitrogens —positively charged nicotinamide nitrogen faced by the odd pair of electrons on imidazole or vice versa. (The relative position of the two nitrogen atoms in question is in accordance with the suggestion of Kosower[4] that the characteristic spectral shift of enzyme-bound NADH is due to the proximity of a quaternary ammonium group.) Again, by representing for convenience a concerted process in discrete stages, it may be seen that a movement of the hydroxyl proton closer to the imidazole nitrogen results in positive charge being placed on both imidazole nitrogens and creates the energetically unfavourable situation of opposing positively charged imidazolium and pyridinium nitrogen (III). In (II), a movement of the imidazolium proton towards the carbonyl leads to the energetically unfavourable situation (V) of opposing odd electron pairs on the two nitrogen atoms in question. Both unfavourable situations may be relieved by charge redistribution as shown in the canonical resonance representations (IV) and (VI) with important consequences concerning the ease of hydride transfer. In (IV), the delocalization of positive charge to the 4-position of the nicotinamide and the creation of partial carbonium ion character should facilitate hydride transfer from the alcohol substrate to that position. In (VI), placement of negative charge at the 3-position, where it may in turn be delocalized by way of the carboxamide carbonyl function, would facilitate reduction of the substrate carbonyl by promoting the expulsion of hydride ion from the 4-position of the dihydronicotinamide. Thus, the aforementioned scheme provides a mechanistic pathway whereby the imidazole ring of histidine can promote rapid hydride transfer in oxidation reduction reactions by 'activating' both the substrate and the coenzyme.

In theory, with the nucleotide fixed in the type of folded conformation necessary for adenine–nicotinamide energy transfer, the imidazole ring of the pyridine nucleotide itself could serve the role postulated for a histidine residue. While the concept of the pyridine nucleotide carrying the potential for its own activation as well as that of the substrate is attractive, intuitively this would appear to assign too passive a role to the enzyme.

Succinylation of Gamma Globulin

THE chemical modification of proteins with succinic anhydride was shown by Habeeb *et al.*[1] to result in an unfolding of the compact conformations of several proteins in neutral aqueous buffer. This was attributed to the large increase in net negative charge produced by the replacement of the positively charged ε-NH_3^+ groups of lysine residues by negatively charged-$NHCOCH_2CH_2COO^-$ groups. An intensive study of the specificity of this reaction and of its conformational effects was made by Cherry[2] with the protein bovine serum albumin; the results have been briefly reported[3]. Utilizing these findings, Klotz and Keresztes-Nagy[4] made the interesting observation that the electrostatic repulsions introduced by succinylation could result in the complete dissociation of non-covalently linked sub-units of proteins, in particular, those of haemerythrin, at neutral *p*H without the addition of any other dissociating agents such as urea or detergent. We have now shown that rabbit γ-globulin, succinylated either before or after partial reduction of interchain disulphide bonds[5], can be separated into its constituent heavy and light peptide chains[5,6] by gel-filtration in aqueous buffers at *p*H near neutrality without the use of detergents[7]. Furthermore, the isolated succinylated heavy and light chains are quite soluble in such buffers, whereas isolated but unmodified heavy chains are insoluble[5].

An experiment in which succinylation was performed after partial reduction of the γ-globulin is described. 500 mg of rabbit γ-globulins (Fraction II, Pentex, Inc., Kankakee, Illinois) was reduced by the method of Fleischman *et al.*[5]. The protein was dissolved in 25 ml. of 0·55 M *tris* buffer, *p*H 8·2, and 0·325 ml. of 2-mercaptoethanol was added. After standing at room temperature for 1 h, the solution was cooled in an ice bath, and to it was added 1 g of iodoacetamide, dissolved in 25 ml. of *tris* buffer and also ice-cooled. After 1 h, the solution was dialysed against 0·2 M potassium chloride in the cold room.

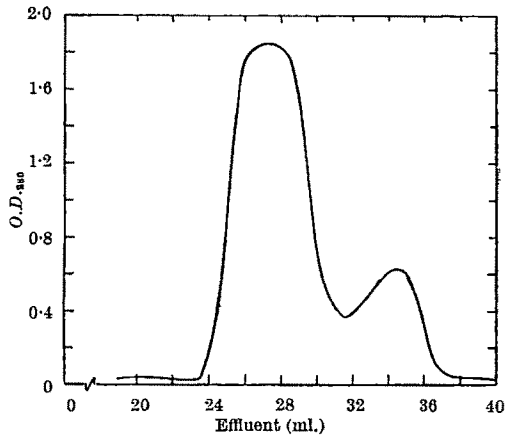

Fig. 1. Gel-filtration of rabbit γ-globulin after mild reduction followed by complete succinylation (see text for details). Column was 'Sephadex *G*-100', 1 × 57 cm column, equilibrated at room temperature with 0·01 M *tris* buffer, *p*H 8·2

Succinylation of this protein solution was carried out by the procedure of Cherry[2]. To the solution, cooled in an ice bath, was added 125 mg of solid succinic anhydride. The stirred solution was maintained at *p*H 8·0 by the careful addition of 5 M potassium hydroxide. The succinic anhydride was completely dissolved after about 40 min, and the mixture was allowed to react at *p*H 8·0 for 1 h thereafter. The solution was then dialysed against 0·01 M *tris* buffer, *p*H 8·2.

Analysis for the completeness of the succinylation of the ε-NH_3^+ groups of lysine was performed by the method of Cherry[2]. This procedure consists of exhaustive dinitrophenylation of the residual ε-NH_3^+ groups of the succinylated protein with dinitrofluorobenzene, hydrolysis in 4 N hydrochloric acid at 105° for 22 h, and determination on a Beckmann model 120 amino-acid analyser of the amount of ε-*N*-(2,4-dinitrophenyl)-lysine present. This compound appears on the short column chromatograms after the arginine peak. The succinylation of the γ-globulin was in this manner shown to be 96–97 per cent complete under the conditions used.

Separation of the succinylated chains was carried out by gel-filtration on a column of 'Sephadex *G*-100' equilibrated with 0·01 M *tris* buffer, *p*H 8·2 at room temperature. A typical elution pattern is shown in Fig. 1. The ratio of areas under the two peaks is 80 ± 2 : 20 ± 2. The heavy chain fraction is completely excluded from the interior of the gel, and the light chain fraction emerges quite close to it. The lower retention of the succinylated chains by the gel as compared with the unmodified chains in 1 M propionic acid may be due to an unfolding of the chains with a consequent enlargement of their molecular domains, or to aggregation. The tendency of the succinylated chains to aggregate is demonstrated by the failure of the chains to separate if gel filtration is carried out at higher salt concentrations; attempts to separate the chains by gel filtration in 0·1 M sodium chloride, 0·1 M *tris* buffer, *p*H 8·0, were not successful.

The two fractions were identified as follows. Each fraction was further purified by a second gel filtration similar to the first and then subjected to amino-acid analysis. The values obtained for each fraction were in satisfactory agreement both with published values[8] and with values obtained from a control which had been withdrawn prior to succinylation and separated into authentic heavy and light chains by gel filtration in 1 M propionic acid[5].

Identical chain separation is achieved if the protein is first succinylated, and then reduced and alkylated, under the same conditions used here. However, the succinylated protein is more susceptible to reduction of its disulphide bonds than is the native molecule. As measured by carboxymethylcysteine content, about nine disulphide bonds are reduced in the former case as compared with 4–5 in the latter[8]. This observation is similar to that of Habeeb[9], who found that succinylation of bovine serum albumin increased the number of disulphide bonds susceptible to mild reduction, presumably as a result of the unfolding of the molecule produced by succinylation.

Succinylation of γ-globulin thus provides a means of obtaining modified heavy and light chains which are readily separable and soluble in a neutral aqueous buffer. Modification is complete and specific for the ε-NH_3^+ groups of lysine[2]. Tryptic digestion of the succinylated chains should produce characteristic fragments terminating in arginyl residues which might prove useful in structural studies of the immunoglobulins.

It has recently been reported by Fuchs and Sela[10] that the reaction of rabbit γ-globulin with *N*-carboxy-D,L-alanine anhydride resulted in polyalanylation of more than 75 per cent of the lysine residues in the molecule. The heavy-chain fraction prepared from polyalanylated γ-globulin was found to be much more soluble at *p*H's near neutrality than an unmodified heavy-chain fraction[10].

PHYSIOLOGY

Denervation and the Electrogenesis of the Sodium Pump in Frog Skeletal Muscle

THE sodium pump in frog skeletal muscle has been found[1] to be electrogenic in experiments in which sodium-rich muscles were immersed in recovery fluid containing 10 mM potassium and the mean membrane potential measured by means of the microelectrode technique[2] during active sodium excretion. It was found that the measured potential, E_m, was greater than the potassium-equilibrium potential, E_K, by about 11 mV, suggesting that uptake of potassium ions may not be tightly coupled to excretion of sodium ions in a 1 : 1 manner[3], but that potassium ions may be drawn into the muscle fibres under the influence of the potential generated by the sodium pump. The electrogenic nature of the excretion of sodium ions in muscle has also been confirmed in other laboratories[4,5].

Experiments have now been carried out with a preparation consisting of companion sartorii connected to the spinal cord of decapitated frog by way of the sciatic nerves. The sartorii were made sodium-rich[6] by overnight immersion in cold potassium-free Ringer–Conway fluid containing 120 mM sodium. The rest of the preparation was in a cold moist chamber similar to that already described for rat muscle[7]. In this fluid, muscle ionic sodium increased from about 25 to 86 m.equiv./kg while ionic potassium decreased from 88 to 36 m.equiv./kg wet weight of muscle. Muscles were then made to excrete

sodium by re-immersion for 2 h at room temperature in Ringer–Conway fluid containing 104 mM sodium and 10 mM potassium. As already described for rat[7], one muscle of each pair was cut free of the nerve before re-immersion in recovery fluid and the sodium ion excretion and potassium ion uptake by innervated and denervated muscles were compared. The results are shown in Table 1.

Table 1. FINAL CONCENTRATIONS OF SODIUM IONS AND POTASSIUM IONS IN MUSCLES AFTER RECOVERY AND E_m MEASURED 10 MIN AFTER RE-IMMERSION OF SODIUM-RICH MUSCLES AND 5 MIN AFTER DENERVATION

Muscles with nerve			Denervated muscles			
Na^+ (m.equiv./kg)	K^+	E_m mV	Na^+ (m.equiv./kg)	K^+	E_m mV	E_K
33·1±2·9	87·9±2·5	63·6±0·9	45·9±2·3	78·9±2·4	72·0±0·9	59·2±3·2

In another series of experiments the mean membrane potential of innervated sodium-rich sartorii was measured about 10 min after re-immersion in recovery fluid. The muscle was then cut free of the nerve and the potential measurements resumed after an interval of about 5 min. One of the innervated companion muscles was analysed for sodium ions and potassium ions immediately after enrichment with sodium ions, while the other in each case was analysed after the potential measurements described. The mean value of E_K for the set of muscles was then calculated and compared with the measured potentials. From the results (Table 1) it appears that the membrane potential of innervated muscles is much closer to E_K, while sodium ion excretion is stimulated at the same time. The sodium pump clearly becomes more electrogenic following denervation of the muscle. The increase in potential observed on denervation is associated with reduction of sodium ion excretion, which might be explained on the basis of reduced potassium ion uptake or permeability. This view is in keeping with the poor accumulation of potassium ions observed in denervated rat muscles during sodium ion excretion as compared with innervated ones[7]. The lower E_m of innervated muscles might be expected to facilitate excretion of sodium ions by reducing the energy barrier to this process[8]. A similar stimulation of excretion of sodium ions has been observed by Horowicz and Gerber[9] when E_m of muscles was reduced by treatment with azide.

Transaminase Deficiency in Alcoholics and Cases of Peptic Ulcer

DURING vitamin treatment of ten male and five female alcoholics it was found that, in the majority of cases, internal rate of conversion of vasodilating nicotinic acid to non-vasodilating nicotinamide was much slower than with controls, as manifested by the incidence of flushing with low doses (50–75 mg nicotinic acid). Very similar results were obtained with five non-alcoholic peptic ulcer cases, duration of flushing being of the order of 30 min and extending over face, neck, arms and sometimes as far as the legs.

Six controls who had not suffered any chronic gastric abnormalities or from alcoholism required doses of 150–200 mg of nicotinic acid to produce similar flushing, but it was further noted that, with both experimental and control subjects, ingestion of food a short time after administration of nicotinic acid induced flushing with lower doses than when fasting. For example, a control subject who required 200 mg to produce a marked flush when fasting needed only 150 mg if food was taken 10–15 min after administration.

The findings suggest that the same enzymes are implicated in the metabolism of foodstuffs and nicotinic acid, food taking the priority of use. In view of present theories of enzyme defects in alcoholics[1] and the frequent occurrence of peptic ulcers in alcoholics, a common enzyme defect is possible. Whatever intermediate steps may be involved, transamination is necessary for conversion of nicotinic acid to nicotinamide, and involvement of a transaminase such as pyridoxal-5-phosphate appears probable.

Preliminary findings from an investigation in progress suggest that in many alcoholics and peptic ulcer cases there is a defective utilization of vitamin B_{12}, lack of which can lead to deficiency of transmethylase[2,3], ribonuclease[4], cytochrome-oxidase[5] and various dehydrogenases[6]. Defective transmethylation could result in deficiency of synthesized pyridoxal-5-phosphate and consequently impaired transamination.

Actinomycin D and the Regulation of Apoferritin Synthesis in Rat Liver

IRON administration increases the net synthesis of apoferritin in rat liver *in vivo*[1]. Correspondingly, liver slices prepared from rats dosed with iron incorporate ^{14}C-leucine into apoferritin *in vitro* more readily than do slices from untreated controls[2]. The mechanism by which the iron acts is unknown, although it has been postulated that intracellular iron in erythroblasts may influence genetic loci[3]. In the following experiments actinomycin *D*, an inhibitor of DNA-dependent RNA synthesis[4], was administered to rats prior to a dose of iron, and liver slices were later tested *in vitro* for incorporation of ^{14}C-leucine into apoferritin. Actinomycin *D* inhibited the stimulatory effect of iron, indicating that derepression of genes and the synthesis of messenger RNA are involved in the regulatory response to the metal.

Male albino rats of the Sherman strain weighing 150–250 g were fasted for 18 h in metabolism cages, lightly anaesthetized with ether, and given 7 mg iron intravenously as iron dextran ('Imferon', Lakeside Lab., Milwaukee). At various intervals thereafter livers were removed from groups of four rats, sliced with a Stadie–Riggs microtome, and 2·0 g of pooled slices incubated in 15·0 ml. medium at 37° C with continuous shaking and gassing with 95 per cent oxygen–5 per cent carbon dioxide. The incubation medium described by Matioli and Eylar[3] was used except that 3·3 μc. of ^{14}C-L-leucine (222 mc./mmole, New England Nuclear Corp., Boston) and 1 μmole carrier L-leucine were added to 15 ml. medium along with 3·0 ml. normal rat serum in place of serum albumin and transferrin. After 3 h of incubation, 1·5 g slices were homogenized in 10 volumes of 0·01 M sodium chloride, the homogenate heated to 72° C for 10 min, and precipitated

proteins removed by centrifugation at 15,000*g* for 20 min. Triplicate aliquots of the supernatant solutions were mixed with 40 μg of carrier crystalline rat liver ferritin and then treated with a rabbit antihorse spleen ferritin antiserum which had been shown to cross-react with crystalline rat liver ferritin[5]. (In later experiments crystalline horse spleen ferritin was used as carrier and found to yield results comparable with the rat liver ferritin.) The immune precipitates were centrifuged after 18 h, washed three times with 10 ml. 0·9 per cent saline, dissolved in 0·5 ml. of 0·25 N sodium hydroxide at 100° C, and aliquots taken for estimation of protein[5] and of radioactivity in Bray's solution[6] in a liquid scintillation spectrometer. Fig. 1 illustrates representative results from two of four experiments. Increased incorporation of ^{14}C-leucine *in vitro* was evident 2 h after iron administration, with a maximal effect, almost ten-fold that of the control value, at approximately 16 h.

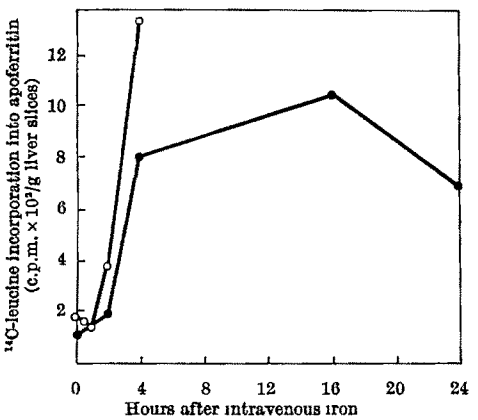

Fig. 1. Incorporation of ^{14}C-leucine into apoferritin by rat liver slices *in vitro* at various times after intravenous iron dextran. Incorporation of ^{14}C-leucine is expressed per gram liver slices. Two experiments are shown, and four rats (weighing 200–300 g) were tested at each time interval

The effect of actinomycin *D* on the iron-stimulated incorporation of ^{14}C-leucine into apoferritin and on ^{14}C-uridine incorporation into ribonucleic acid was then studied. The following three groups of four rats were tested in each experiment: untreated, treated with iron dextran as here, or given 1–4 μg/g body-weight of actinomycin *D* intraperitoneally or intravenously 30 min before iron dextran. 4 h after iron the livers were removed and pooled slices tested with ^{14}C-leucine as already outlined and, separately, under identical conditions except that uridine-2-^{14}C (25 mc./mmole, New England Nuclear Corp.) replaced radioactive leucine. Slices incubated with ^{14}C uridine were later homogenized in ten volumes of isotonic saline, and the method of Schneider[7] used to precipitate, wash, and extract nucleic acids with hot trichloroacetic acid. The extracts were washed three times with equal volumes of ether to remove trichloroacetic acid (which quenches in the liquid scintillation solution used) and aliquots taken for estimation of ribose[7] and of radioactivity in Bray's solution. Table 1 summarizes the results of four experiments. In each instance actinomycin *D* clearly inhibited incorporation of uridine into RNA and of leucine into apoferritin, and the effects were comparable quantitatively. Thus the greatest inhibition of incorporation into apoferritin, 91·2 per cent in experiment 4, corresponded to the greatest decrease in incorporation into RNA, 80·3 per cent.

The results indicate that DNA-dependent synthesis of messenger RNA is a necessary step in the events which are initiated by iron and lead to increased synthesis of apoferritin. The initial site of action of the iron remains unknown, although one possibility is that it directly affects a regulatory gene[8]. Further analysis of the control of apoferritin synthesis *in vitro* may clarify the nature of the genetic regulation, a type of control which appears to underly the action of certain hormones and other substances[9].

Table 1. EFFECT OF ACTINOMYCIN *D* ON IRON-STIMULATED INCORPORATION OF ^{14}C-LEUCINE INTO APOFERRITIN AND ON ^{14}C-URIDINE INCORPORATION INTO RNA BY RAT LIVER SLICES *in vitro*

	Exp. group	Incorporation ^{14}C-leucine into apoferritin (c.p.m. × 10^3 per g liver slices)		Incorporation ^{14}C-uridine into RNA (c.p.m. × 10^3 per μmole ribose)	
(1)	No iron	2·32		2·60	
	Iron	8·62		3·40	
	Actinomycin + iron*	3·93		1·44	
	Percentage inhibition		54·4		57·7
(2)	No iron	2·18		6·52	
	Iron	15·92		5·48	
	Actinomycin + iron*	7·41		1·71	
	Percentage inhibition		53·4		68 7
(3)	No iron	1·28		4·79	
	Iron	4·88		5·69	
	Actinomycin + iron	2·74		2·52	
	Percentage inhibition		43·8		55·7
(4)	No iron	0·73		6·79	
	Iron	5·06		5·06	
	Actinomycin + iron	0·44		0 99	
	Percentage inhibition		91·2		80·3

* Doses (μg/g body-weight) of actinomycin *D* were 1 μg (intraperitoneal) in experiment 1, 2 μg (intraperitoneal) in experiment 2, and 4 μg (intravenous) in experiments 3 and 4.

Demonstration of Endogenous Pyrogen in Afebrile Rabbits

A VARIETY of environmental factors, including position, are known to influence temperature regulation in experimental animals. Rectal temperature will fall 1°–2° C over a 2-h period in rabbits fastened to a board[1]. In addition, securely restrained rabbits in a normal, standing position will develop hypothermia of as much as 2·7° C during a 30–90 min period and exhibit reduced febrile responses to pyrogens when compared to 'free' animals[2]. Fekety recently reported a fall in baseline rectal temperatures when rabbits were shorn, restrained supine, or chilled; furthermore, large doses of endotoxin, adrenaline, or endogenous pyrogen failed to elicit fever[3]. It was postulated that the hypothermia resulted from increased heat loss, since covering the shorn and supine rabbits with blankets restored normal pyrogenic responsiveness[3]. As some of these differences in febrile reactivity might be due to alterations in the production of endogenous pyrogen, this possibility was investigated.

New Zealand albino rabbits of either sex weighing approximately 2 kg from the same colony (National Institutes of Health) were used. Animals were housed in air-conditioned rooms and the experiments were performed in the same environment. Upright animals were restrained with loosely fitting collars in wooden stocks which permitted freedom of movement of their torsos; prone animals were securely restrained with their legs

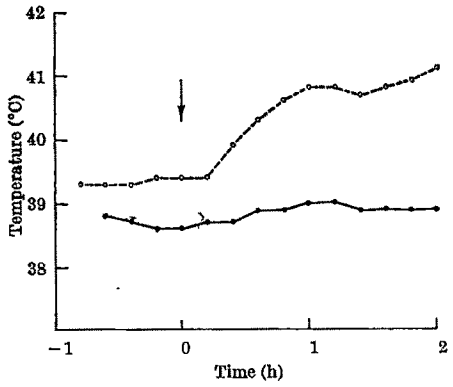

Fig. 1. Mean temperature responses of 6 upright (○ - - - ○) and 5 prone (●——●) rabbits to 5 μg of endotoxin given at zero hour (arrow). Animals were exsanguinated at 2 h

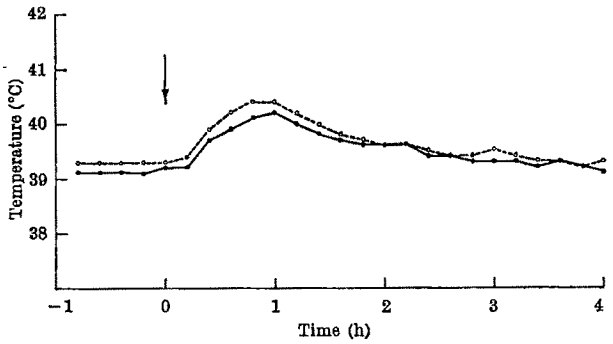

Fig. 2. Mean temperature responses of normal rabbits given sera obtained at 2 h from animals in Fig. 1; 10 c.c. of pooled sera from upright (○ - - - ○) and prone (●——●) rabbits administered at zero hour (arrow). Curves represent mean responses of 8 animals (upright donors) and 5 animals (prone donors)

extended. Both groups were trained in their respective positions for 3–5 h on the day before the experiments. Temperatures (°C) were monitored with thermistors connected to a recording telethermometer and inserted 4–6 in. into the rectum. *E. coli* endotoxin (Difco) was dissolved in sterile, pyrogen-free saline at a concentration of 5 μg/ml. prior to intravenous injection into a marginal ear vein. All equipment was sterile and pyrogen-free. Endogenous pyrogen was prepared as described by Atkins and Wood[4]: animals were injected with 5 μg of endotoxin and bled by cardiac puncture 2 h later. After clotting, serum was separated by centrifugation, pooled (2 animals per pool), stored at 4° C and used within 3 days. Following incubation for 1 h (37° C), 10 c.c. portions were injected into a marginal ear vein of normal recipient animals. Fever index for each animal was determined by plotting temperature versus time on 1 × 1 in. standard graph paper (1 h and 1 deg. each equal 1 in.), and the area in cm^2 under the 5-h fever curve was measured with a compensating polar planimeter.

Following the administration of 5 μg of endotoxin, upright rabbits developed fever, in contrast to prone rabbits which remained essentially afebrile (Fig. 1). Despite these differences, sera obtained 2 h after endotoxin injection from these two groups contained similar amounts of endogenous pyrogen (Fig. 2). Mean fever indices of the animals that received the endogenous pyrogen were not different: mean fever index ± standard error of 8 normal rabbits receiving sera from the upright (febrile) animals was 10·1 ± 0·82 cm^2, and that of 5 rabbits receiving sera from the prone (afebrile) rabbits was 11·5 ± 0·79 cm^2.

In addition, 2 prone rabbits bled through femoral arterial catheters experienced a fall in white blood cell count to 25 per cent of control values within 10 min after endotoxin injection, which persisted throughout the 2-h period. These changes in leucocytes are similar to those noted in upright animals following challenge with endotoxin. These findings would support the concept that endogenous pyrogen is derived from leucocytes during the leucopenic response to endotoxin and that this mechanism is unaffected by position or lack of febrile response in restrained rabbits.

These data demonstrate the production of endogenous pyrogen in the absence of fever and suggest that the lack of fever is due to either a decreased responsiveness of the thermoregulatory centres or an inability to conserve heat normally. Increased heat dissipation could be due solely to positional factors through the exposure of relatively hairless areas, as suggested by others[3], or to the increase in body surface area added by stretching the animals out; these explanations are supported by the fact that merely covering the animals will restore pyrogenic responsiveness[3]. It is noteworthy, however, that since a wide variety of positions will affect temperature, a more complex mechanism than simply heat loss may be responsible for the observed changes. All the experiments described, including our own, which demonstrated altered febrile reactivity, used animals which were securely restrained; thus, immobilization, regardless of position, may have a profound influence. Since the administration of cortisone will block the febrile response to endotoxin in normal animals[5], it is possible that the magnitude of the endogenous adrenocortical response in restrained animals is sufficient to suppress fever.

We thank Mr. J. Edelin for expert assistance.

Growth Hormone Secretion in Response to Stress in Man

A WIDE variety of emotional and physical stimuli result in increased adrenocortical activity. Thus plasma cortisol-levels rise in response to trauma, surgery, fever and hypoglycaemia[1–3]. This has been attributed to a stress control mechanism which depends on the integrity of a cerebro-hypothalamo-pituitary-adrenal pathway and overrides the normal 'negative-feedback' control mechanism[4]. An increased secretion of growth hormone has been shown during insulin and tolbutamide induced hypoglycaemia, during exercise and during acute or chronic starvation[5–8]. This has been attributed to an increased demand for energy substrates and to be mediated via the hypothalamus. The possible role of stress in relation to growth hormone release does not appear to have been considered.

Emotional stress. Our interest in this possibility arose from the findings in a medical student, who was told that he had received a large dose of insulin and would experience severe hypoglycaemic symptoms. In fact, saline and not insulin had been injected. His plasma sugar remained unaltered, but there was a demonstrable increase in his plasma cortisol measured fluorimetrically[9] and growth hormone determined by radioimmunoassay[10] (Table 1*A*). Saline injection in four other control subjects, without prior suggestion, produced no changes in plasma sugar, cortisol or growth hormone.

Pyrogen. In two male and two female subjects we have shown an increase in growth hormone secretion to pyrogen

Table 1. RESPONSE OF PLASMA GROWTH HORMONE TO STRESS

	Control period	Min after injection 30	60	90	120
A Emotional stress; male subject*	1·1	5·2	10·5	—	8·7
B Pyrogen; 2 males and 2 females	3·0 ±2·8†	3·1 ±2·8	3·1 ±2·8	18·9 ±4·5	18·4 ±11·9
C Pyrogen + glucose; female subject	<1·0	<1·0	3·7	10·7	7·0
D Lysine 8-vasopressin; 3 male subjects	<1·0†	<1·0	<1·0	1·8	2·0
E Lysine 8-vasopressin; 2 female subjects	2·0 1·1	6·3 11·7	32·0 21·4	21·7 21·8	6·6 25·2

Results for plasma growth hormone expressed as μmg/ml.
* Injected with saline.
† Mean level and where possible the standard deviation.

(0·005 μg/kg body-weight, Organon) as evidenced by elevated circulatory growth hormone levels 90 min after injection (Table 1*B*). The plasma cortisol increased at the same time, but the plasma sugar did not change significantly. The responses in the male and female subjects were not different. The results suggest that a pyrogen-induced stress stimulates both pituitary growth hormone and ACTH secretion which is not due to a measurable hypoglycaemia. Similar rises in circulating growth hormone with the maintenance of normal blood sugar levels have been found after exercise in the fasting state. This has been attributed to the increased metabolic demands for lipid substrates stimulating secretion since the elevated plasma growth hormone levels are suppressed by glucose[7,11].

Pyrogen and glucose. The growth hormone response to pyrogen would appear to involve a different mechanism not previously demonstrated since it was not suppressed by a continuous intravenous infusion of glucose (Table 1*C*). Thus a rise in plasma sugar levels from 90 to 135 mg/100 ml. was observed during the 60–120 min period after the injection of pyrogen when growth hormone secretion was stimulated.

Lysine 8-vasopressin (LVP). The adrenocortical response to stress requires the secretion of corticotrophin-releasing factor (CRF) from the hypothalamus and thence pituitary ACTH release and adrenal cortisol secretion. Studies were carried out using lysine 8-vasopressin, a compound having corticotrophin-releasing activity in man[12], to determine whether it was possible in normal subjects to stimulate cortisol secretion without a concomitant stimulation of growth hormone secretion. In five normal subjects, infusion of synthetic LVP (Sandoz) at the rate of 5 P.U./h for 2 h produced the expected elevation in plasma cortisol-levels, the individual maximum cortisol increments ranging from 8·9 to 25·9 μg/100 ml. The infusion had no significant effect on growth hormone levels in the three male subjects (Table 1*D*), but a marked increase was observed in the two female subjects studied (Table 1*E*). There was no association between the presence or absence of a response in growth hormone to LVP and the rises in plasma cortisol or the levels of plasma sugar which were essentially unchanged throughout the test. Further work is required to confirm and elucidate the apparent sex difference in growth hormone response to LVP. It may be noted, however, that oxytocin and lysine vasopressin increase plasma free fatty acids in puerperal women and female dogs but cause decreases in male dogs[13,04].

Summarizing, stimulation of growth hormone secretion associated with adrenocortical activity occurred in response to emotional stress and to the injection of pyrogen. This was not associated with hypoglycaemia. The plasma growth hormone response to pyrogen secretion was not suppressed by an induced hyperglycaemia. Stimulation of cortisol secretion by lysine 8-vasopressin was accompanied by a rise in plasma growth hormone levels in women but not in men. Plasma sugar-levels were unchanged in both men and women.

We thank Dr. G. F. Marrian and Dr. V. Wynn for their support of this work, and Mrs. J. Gray and Miss J. Riccardo for skilled technical assistance. We thank Dr. V. H. T. James for the analyses of plasma cortisol used in this investigation.

Note added in proof. Since this letter was submitted, Glick, Roth, Yalow and Berson (*Rec. Prog. Horm. Res.*, **21**, 241; 1965) have reported an elevation of plasma growth hormone after major surgery, not suppressed by glucose administration

PHARMACOLOGY

Inhibition of Ribonucleic Acid Synthesis in Mouse Skin by Actinomycin *D* and 7,12-Dimethylbenz[*a*]anthracene

IT has recently been demonstrated that the initiation of skin tumorigenesis by 7,12-dimethylbenz[α]anthracene (DMBA) is dramatically inhibited by topical applications of actinomycin *D*[1,2]. In view of the well-known inhibitory action of actinomycin *D* on DNA-dependent RNA synthesis[3], it was proposed that this observation helps support the hypothesis that the early events of chemical tumorigenesis involve alterations in the expression of specific genetic information. In the present study we describe the effect of topical applications of actinomycin *D*, of DMBA, and of the two combined on the synthesis of RNA in mouse skin. The experimental conditions employed exactly simulate those used to inhibit tumour formation[1].

As pointed out by Sinclair and McCarter[4], it is not possible to incorporate sufficient radioactivity into the RNA of skin by administering radioactive ribonucleosides intravenously, intraperitoneally, or subcutaneously to constitute a reliable assay of RNA synthesis. We were able, however, to obtain a highly reproducible measurement of RNA synthesis using a slight modification of the method described by Sinclair and McCarter[4]. This involved incubating narrow strips of full-thickness skin (5 mm × 3 cm), excised from treated areas of the back of the mouse, in 5 ml. of Eagle's medium containing 50 μc. of ^{3}H-uridine (7·1 c./mM). The incubation was carried out at 37° C in a shaking water bath for varying lengths of time. At the end of such time, the reactions were terminated by removing the excised pieces of skin from the incubation medium and either freezing at −20° C for biochemical analysis or fixing firmly mounted pieces in alcohol–acetic acid (3 : 1) for eventual sectioning and autoradiography.

The incorporation of ^{3}H-uridine into skin RNA was determined both by autoradiography of 3-μ-thick sections of skin and by a previously described biochemical procedure[5]. That incorporation of ^{3}H-uridine occurs exclusively into RNA is indicated by the data in Fig. 1, in which it is shown that ribonuclease action or treatment with

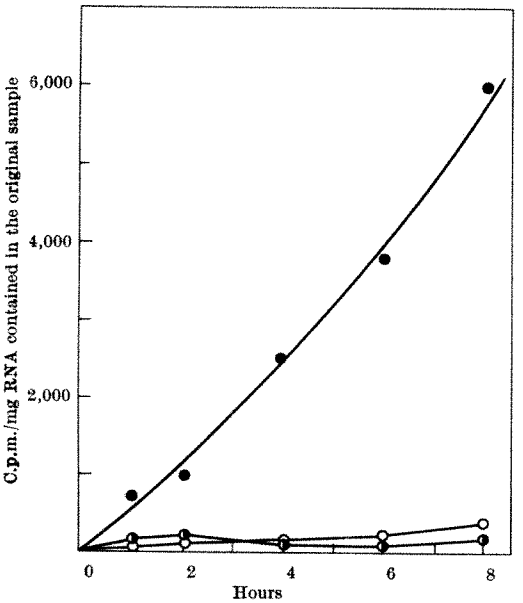

Fig. 1. Kinetics of the incorporation of ^{3}H-uridine into RNA of mouse skin. Narrow strips of full-thickness skin were removed from the backs of previously shaved, random bred Swiss mice and incubated as described in the text. After the appropriate incubation time, the strips were removed, frozen, and stored for two to three days, then thawed and freed of the panniculus carnosus and adipose tissue. The resulting skin was minced with scissors and exhaustively ground in 5 ml. of 0·01 M phosphate buffer, *p*H 7·0, containing 0·14 M sodium chloride using a power-driven glass-teflon tissue grinder. An equal volume of 20 per cent trichloroacetic acid was added and each sample washed as described previously (ref. 5). Closed circles represent the acid precipitable radioactivity of washed samples following an incubation at 37° C in 2 ml. of phosphate-saline, *p*H 7·0, for 20 min. Open circles represent acid-precipitable radioactivity in the same samples incubated as above except that 200 μg of ribonuclease was added at the start of each incubation. Half closed circles represent acid-precipitable radioactivity from those samples which were suspended in 0·3 M potassium hydroxide and incubated at 37° C for 18 h. Radioactivity and RNA determinations were conducted as previously described (ref. 5). Each point represents the average value obtained from four independent determinations

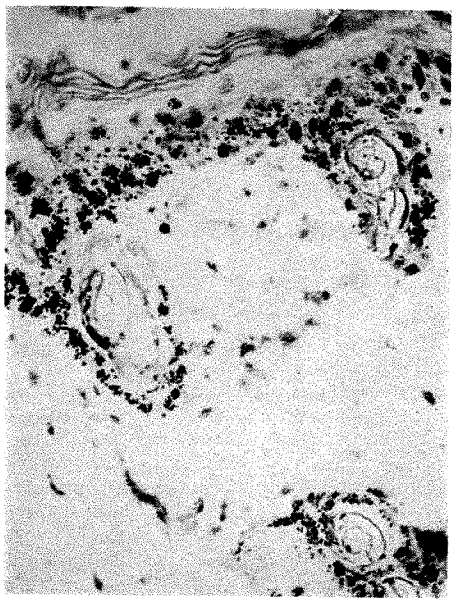

Fig. 2. Autoradiograph of a section of mouse skin. Narrow strips of skin were incubated for 4 h *in vitro* with Eagle's medium containing ^{3}H-uridine. Deparaffinized sections (3μ) of skin, washed in 5 per cent trichloroacetic acid at 0° C for 5 min, were covered with Kodak 'AR10' stripping film. After 3 weeks of exposure, slides were processed and stained through the emulsion with toluidine blue. Note that the heavy labelling is restricted to the cells of epidermis and hair follicles

0·3 M potassium hydroxide under conditions known to hydrolyse RNA preferentially[6] releases essentially all the radioactivity into an acid soluble form.

The autoradiograph shown in Fig. 2 clearly illustrates that only the interfollicular and follicular epidermal cells are significantly labelled. The cells of the dermis are virtually unlabelled and consequently do not contribute appreciably to the radioactivity found in the RNA fractions of skin such as those shown in Fig. 1 and Table 1. RNA synthesis, therefore, is principally associated with those cells known to constitute the actual tumour or papilloma rather than with dermal cells which are not an integral part of the tumour at early stages of development[7].

As shown by the data in Table 1, a single small dose of DMBA, equivalent to that used to initiate the tumorigenic process[1], partially inhibits the synthesis of RNA at early time. By the third day following the application of DMBA, however, full recovery of RNA synthesis has occurred. In direct contrast to the relatively rapid onset and short duration of the inhibitory activity of DMBA is the observation that the maximal inhibitory effect of actinomycin *D* on the synthesis of RNA is not realized until the third day and that recovery of RNA synthesis does not begin until 11 days after its initial application. Furthermore, the data in Table 1 indicate that, at the dosage used, DMBA does not significantly influence the duration or extent of inhibition of RNA synthesis as produced by six topical applications of actinomycin *D*.

Table 1. INHIBITION OF THE INCORPORATION OF ^{3}H-URIDINE INTO THE RNA OF MOUSE SKIN

Time after first application	Percentage inhibition DMBA	Act *D*	DMBA + Act *D*
8 h*	—	0 ± 6	—
16 h	18 ± 5	20 ± 5	15 ± 5
24 h	22 ± 5	30 ± 2	25 ± 7
2 days	0 ± 5	—	—
3 days	6 ± 5	84 ± 5	72 ± 5
4 days	0 ± 5	81 ± 4	78 ± 3
5 days	—	90 ± 3	—
8 days	0 ± 6	86 ± 7	86 ± 2
11 days	0 ± 5	81 ± 5	79 ± 2
14 days	0 ± 5	0 ± 3	15 ± 3
21 days	0 ± 5	—	5 ± 5

* In this experiment only the first three actinomycin *D* treatments were given.

To the shaved back of general-purpose Swiss mice, either a single dose of 15 μg of DMBA in 0·2 ml. of acetone was applied to the entire back, or 15 μg of actinomycin *D* in 0·2 ml. of acetone was applied 2, 5, and 8 h before and 2, 5, and 8 h after the application of DMBA. When actinomycin *D* alone was applied, the same dose and time sequence was used except that acetone was substituted for DMBA. The controls, on which the percentages shown above are based, were treated similarly with acetone. Before excising a narrow strip of skin for the incubation, the backs were swabbed with 95 per cent ethanol to remove any excess actinomycin *D* or DMBA. Biochemical analysis of the incorporation of ^{3}H-uridine into skin RNA was carried out as described in Fig. 1. Each value listed above represents the average inhibition found in from 3 to 8 determinations.

It is clear from these observations that the synthesis of RNA has not been inhibited by actinomycin *D* at the time of DMBA application. In fact, significant inhibition by actinomycin *D* is delayed 24 h, and then the degree of inhibition is equivalent only to that produced by DMBA alone. This suggests that 'initiation', a term which designates the early irreversible events of skin tumorigenesis, is not complete until at least 24 h following the application of the hydrocarbon, since actinomycin *D* treatment at that time successfully blocked tumour formation[1]. Furthermore, it has been shown by Bates *et al.*[2] that actinomycin *D* application 1 day after DMBA treatment is at least as effective in inhibiting tumour formation as the simultaneous application of both agents. It therefore seems probable that the initiation process is not complete until at least 48 h after DMBA application. In contrast to the apparent delay in the complete initiation of tumorigenesis, DMBA functions rapidly to inhibit the synthesis of RNA in mouse skin. The inhibitory action is transitory, however, and the completion of the initiation process appears to occur after the diminution of this effect. Therefore, it seems highly probable that, although DMBA inhibits RNA synthesis, as was recently shown by Sinclair and McCarter[3], this action by itself does not constitute the irreversible event of chemical tumorigenesis.

Brookes and Lawley have observed that the binding of DMBA to DNA is more persistent than is its binding to protein which is maximal during the first 48 h (ref. 8). Since our findings suggest that the first irreversible event of tumorigenesis occurs 48 h after the application of DMBA, the binding of DMBA to DNA sites may be related

to this event. Their observation that a good correlation exists between the carcinogenic potency of various hydrocarbons and the extent to which these hydrocarbons bind DNA is consistent with the above suggestion.

IMMUNOLOGY

Appearance of Natural Antibodies in Young Rabbits

NATURALLY occurring antibodies to antigens of erythrocytes, tissues such as liver, and microbes are invariably detectable in the serum of fully grown animals but are not found in the serum of the new-born. Whether these antibodies arise as a result of normal physiological maturation or as a result of inapparent immunization has puzzled immunologists for many years. There is evidence that the blood group and microbial antibodies may be formed as a response to ingested antigens, since their production has been prevented in some cases by rearing the animals in a germ-free environment. Germ-free chicks, for example, promptly developed antibodies to blood group B antigen after the oral administration of *Escherichia coli* 086, an organism with blood group B antigenic determinants[1]. The phenomenon of naturally occurring complement-fixing serum substances reactive with extracts of mammalian tissue, including an animal's own tissue, is not readily explained[2,3]. It is possible that these substances, which are serum globulins, are not antibodies formed in response to antigenic stimulation. When combined with tissue for which they have an affinity, they may conceivably be aggregated and thereby fix complement[4].

There are certain difficulties in accepting the thesis that all naturally occurring antibodies arise as a result of inapparent immunization. Obviously, immunization may account for some, but not all, of these antibodies. The production of antibody to blood group B substance in germ-free animals by immunization with *E. coli* 086 does not exclude the possibility that antibodies may arise by other mechanisms in addition to immunization. The low levels or absence of bactericidal antibodies in the germ-free animal may be explained also as a result of physiological abnormalities[5] related to their development in an unnatural environment. In addition, germ-free animals with minimal levels of gamma-globulin do not always have lower levels of bactericidal or phage-neutralizing antibodies than their litter-mates reared in a conventional environment[6,7]. These observations are not conclusive in that germ-free animals are subjected to a variety of antigenic substances in sterile foods and viruses. Nonetheless, pelagic whales, the bacterial flora of which lack intestinal coliform organisms, possess bactericidal antibodies against *E. coli* in titres equal to those of human subjects[8]. Finally, it has been pointed out that the naturally occurring blood group antibodies in man such as anti-P_1 and anti-Le^a react more strongly at lower temperatures, whereas antibodies arising after an identifiable stimulus such as anti-Rh react more strongly at 37° C (ref. 9) and normal rabbit bactericidal antibodies may be heat labile (56° C for 30 min) in contrast to the heat stability of immune bactericidal antibody[10].

The present communication attempts to investigate this problem further by determining the time of appearance of four antibodies directed against three markedly different antigens. Naturally occurring bactericidal, bacteriophage neutralizing and complement-fixing antibodies against normal rabbit and rat tissue were titrated in the serum of healthy, non-immunized rabbits from a few weeks after birth until the rabbits had reached maturity. The methods used have previously been described[3,11,12].

Results of representative titrations of serum collected at approximately 10-day intervals over a 217-day period from an individual rabbit are given in Table 1. In no case was antibody detectable before rabbits were 28 days of age. Bactericidal and phage neutralizing titres steadily increased as the animal aged. Complement-fixation titres became detectable at ≤9 days of age and reached what appeared to be a maximum at 59 days of age. Bleedings obtained beyond 217 days, up to 270 days, revealed no further increase in titre and these results were not included in the table. Several other rabbits the sera of which were similarly tested gave essentially the same results.

Table 1. APPEARANCE OF NATURAL ANTIBODIES IN RABBIT

Age of rabbit (days)	Bactericidal titre* against *Shigella dysenteriae*	Neutralization titre† against coliphage *T2*	CF antibody titre‡ against: Rabbit liver	CF antibody titre‡ against: Rat liver

* Reciprocal of serum amount required to kill 50 per cent of an inoculum of about 2×10^7 cells of the organism (ref. 11).
† Reciprocal of serum amount required to neutralize 50 per cent of 10^3 *T2* coliphage particles (ref. 12).
‡ Antigens were saline extracts of the tissue in a complement-fixation procedure previously described (ref. 3).

Many mammals synthesize relatively little gamma globulin at birth and the ability to produce these globulins develops early in post-natal life[13,14]. From the data of Table 1, it can be seen that antibodies to the various antigens all appeared at about the same time. The fact that antibody was first detected by phage neutralization is probably due to the greater sensitivity of this system. It does not seem likely that the growing rabbit would simultaneously encounter antigens that induce antibody formation toward *Shigella*, *T2* coliphage, rabbit or rat liver. If natural antibodies are merely globulin molecules with affinities toward any antigen to which the animal can respond[15], the production of natural antibodies might reasonably be expected to parallel the appearance of immunoglobulins in the serum. It is possible that rabbits aged 40 days encounter a wide spectrum of antigenic determinants found in bacteriophage protein, cell walls of *Shigella*, and the cytoplasmic constituents of mammalian tissue. More likely, however, is the postulate that certain globulins arise at this time as a result of normal physiological maturation and that globulins react with certain antigens because of chance chemical correspondence with certain specific combining groups. The appearance of tissue complement-fixing 'auto-antibodies' at the same time as the bacterial and viral antibodies also suggests that these substances may be formed by related mechanisms.

The results of this investigation and other considerations indicate the possibility that natural occurring antibodies may not always arise as a result of immuniza-

tion. It may not be possible to obtain an experimental answer to the question of the origin of the naturally occurring antibodies due to the fact that animals live in a microbial world with highly antigenic substances that are necessary for their development.

Antibody Production by Single Spleen Cells: a Comparative Study of the Cluster and Agar-plaque Formation

DURING the past few years, two new methods have been described for use in investigating *in vitro* production of antibodies against sheep erythrocytes by isolated cells. In the first method[1,2] a suspension of spleen cells is mixed with sheep erythrocytes, embedded in agar or carboxymethylcellulose and incubated with guinea-pig complement. Under these conditions, plaque formation occurs as a consequence of the production of haemolysins by certain spleen cells. With the second method[3,4] a suspension of spleen cells is incubated with sheep red blood cells, but the cells are not embedded in a semi-solid medium. In this environment clusters of agglutinated sheep erythrocytes are formed around a number of spleen cells. In the present investigation the results obtained by these two methods are compared and the observed differences are discussed.

The agar-plaque technique was performed as described by Jerne[5]. For the investigation of the cluster formation our previously described technique[3] was slightly modified: the L_1 medium was replaced by Eagle's medium with 5 per cent calf serum (absorbed with mouse erythrocytes) and during incubation the tubes were not agitated but the cells were allowed to settle on the bottom of the slanting culture tube. These modifications resulted in a significant increase in the number of clusters formed.

First the possibility was investigated that cluster formation in this system was due to the absorption of cytophylic antibodies[6] on certain spleen cells. A pooled suspension of spleen cells from non-immunized mice was divided in four aliquots containing nine million cells each. Two samples suspended in 1 ml. medium containing 0·3 ml. normal mouse serum were kept in melting ice for 1 h[6]; the other two samples were kept in the same way in medium containing mouse-anti-sheep serum. The haemagglutinating titre of the antiserum was in two successive experiments 1 : 3,200 and 1 : 25,600 respectively. After incubation the cells were washed in the cold until no or only slight agglutinating activity was found in the washing fluid. The washed suspensions were incubated in the usual way with sheep erythrocytes. In both experiments, between 0·04 and 0·3 per cent of the spleen cells kept in control serum and between 0·1 and 0·3 per cent of the cells kept in antiserum formed clusters. An identical treatment of spleen cells from immunized mice neither increased nor decreased the number of cluster-forming cells. Injection of non-immunized mice with strong haemagglutinating antisera, causing a titre in the blood of these animals of 1 : 640, resulted in no increase of the number of cluster-forming cells in the spleen, when these animals were killed 24 h after the last injection. All these figures were very close to the values found in non-immunized control mice ($0{\cdot}15 \pm 0{\cdot}07$ per cent). More evidence against the assumption that cluster formation is only due to antibodies adhering to the surface of some spleen cells was provided by the observation that the cluster of sheep erythrocytes around the spleen cells often consisted of several cell layers. It seems reasonable to assume that antibodies absorbed on the cellular surface could cause only the agglutination of one layer of erythrocytes. The number of layers could be determined by adding a drop of acetic acid to the suspension in the haemocytometer during microscopical observation. The gradual lysis of the erythrocytes revealed that the number of erythrocyte layers surrounding the nucleated cell sometimes amounted to four. Moreover, the nucleated cell could sometimes be loosened from the clustered erythrocytes by mild shaking, while the cluster of erythrocytes remained intact.

The question arose whether plaque and cluster formation are two manifestations of the same phenomenon or belong to different processes in antibody formation. If the first supposition holds true it should be possible to convert a cluster into a plaque by the addition of complement. This possibility was investigated by two different methods:

(*a*) Guinea-pig complement was added to a cluster containing suspension of spleen cells and incubated at 37° C. During microscopical observation of at least 2 h no perceptible lysis of clustered sheep erythrocytes was observed nor was a significant decrease in the number of clusters found. When, however, a small amount of antiserum was added to the suspension, both free and clustered sheep erythrocytes were lysed.

(*b*) Spleen cells from immunized mice were first incubated for 30 min in a suspension with sheep erythrocytes and thereafter this cluster containing suspension was mixed with agar and poured on a Petri dish. With a suitable magnification the already formed clusters embedded in the agar were clearly visible. In a certain area of the plate all clusters were marked by a small circle, scratched in the bottom of the plastic Petri dish. A second incubation and the addition of complement resulted in a clear-cut plaque formation on the agar plate (Fig. 1). However, of a total number of 913 clusters so marked, none was found to form a plaque after incubation with complement. From this observation it can be concluded that the antibody producing cells produce either a plaque or a cluster. Production of lysis and agglutination by the same cell, if it occurs, must be a very rare phenomenon.

In order to investigate the relation between cluster and plaque formation, the haemolysin and haemagglutinin titres and the numbers of cluster- and plaque-forming cells in the spleen of $(DBA/2 \times C57BL)F_1$ and $ND2$ mice were determined at different time intervals following a single intravenous or intraperitoneal injection of sheep erythrocytes. (The $ND2$ mice were obtained from the Radiobiological Institute, Organization for Health Research TNO, Rijswijk (Z.H.).) So far as plaque formation is concerned, the data are in reasonable agreement with the results of Jerne[5] and Friedman[7]. The cluster formation and the titre of the haemagglutinating antibodies follow a somewhat different course (Table 1). The numbers of plaque-forming cells and the haemolysin

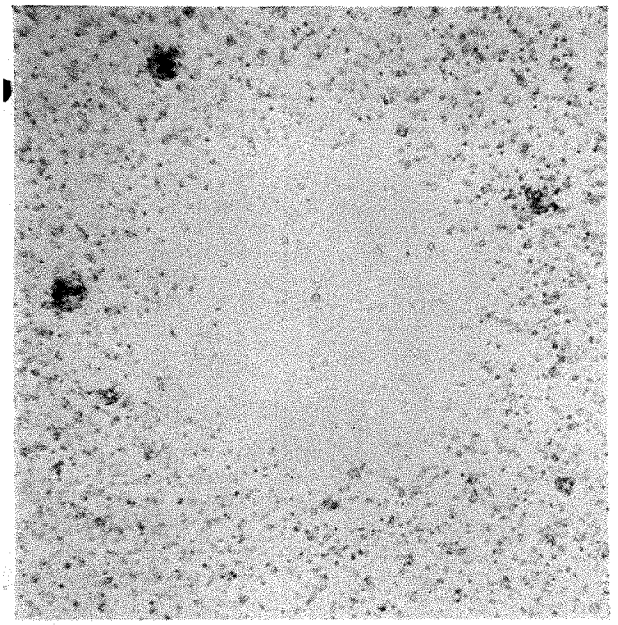

Fig. 1. Microphotograph of an agar plate containing both clusters and plaques formed by spleen cells from mice immunized with sheep red blood cells

titres show a clear-cut tendency to decrease after a sharp rise at about the fourth day, whereas the numbers of cluster-forming cells and the haemagglutination titres level off at about the sixth day. The *ND2* mice which received an intraperitoneal injection of sheep cells show this difference even more pronounced than the $(DBA/2 \times C57BL)F_1$ mice which received an intravenous injection (Table 2).

In smears made of cluster containing spleen cell suspensions and stained with either May–Grünwald and Giemsa or with methyl green–pyronin, cluster-forming cells could be identified by a rim of adherent erythrocytes around the cell. It was found that nearly all observed cluster-forming cells had the morphology of lymphoid cells with a preference for the younger forms. All these cells showed a positive pyroninophilic cytoplasm. Cells which had ingested carbon particles after intraperitoneal injection of indian ink were in a few instances found to form small clusters. Polymorphs, on the other hand, were never surrounded by agglutinated erythrocytes.

11	72	23,000	1 : 141	1 : 1,024

* The mice were intraperitoneally injected with 0·5 ml. of a 20 per cent suspension.
† Titre of 50 per cent haemolysis.

The results indicate that cluster formation is caused by an antibody producing cell. Since plaque formation also is caused by antibody production the results suggest that two different classes of cells are present, one class producing haemagglutinating, the other haemolysing, antibodies. These findings are supported by the results of Talmage and others[8–10], which indicate that antisera against sheep erythrocytes may contain components which differ in haemolytic and combining activity. The relatively high number of cluster-forming cells in the spleen with the number of plaque-forming cells in the spleen may reflect either a higher sensitivity of the cluster method or a real difference in the mechanism of these two systems.

Part of this work was performed under contract with the European Atomic Energy Commission, 51–53 Rue Belliard, Brussels, Belgium.

PATHOLOGY

Effect of Alimentary Lipaemia on the Glycoproteins and the Congo Red-binding Capacity of Albumin in Healthy and Atherosclerotic Individuals

BENNHOLD's investigations[1] demonstrated that Congo red, which is known to be bound by albumin, injected intravenously in patients suffering from analbuminaemia, is eliminated from the circulating blood at a considerable rate and that, following the injection of albumin preparations, it reappears in the blood stream. This phenomenon illustrates the significance of albumin as a carrier protein. In the mechanism regulating the release of intravenously injected dyes from the blood stream the processes of adsorption between the dyes and the plasma proteins and the vascular or extravascular proteins, respectively, play a decisive part. On the basis of the foregoing it can be stated that the physico-chemical interactions occurring between the serum proteins and the transported substances make it possible for the latter: (1) to be eluted from the tissues and to become adsorbed by the carrier protein; (2) to be transported in bound form; and (3) to be discharged from the carrier protein at a site which possesses a greater affinity for the transported substance (the site of utilization, storage or excretion and elimination).

Considering that, on one hand, the transport capacity of proteins is limited, while on the other there is competition between the various substances for the available transport surfaces, both the reduction of the transport capacity of the plasma proteins, as well as any excessive increase in the amount of one of the substances transported, may lead to the appearance of certain pathological

phenomena similar to thesaurismosis. As an example illustrating this, we may mention the following pathological processes. The discharge of the carrier protein loaded with non-metabolized bilirubin (which has not been excreted by the liver), due to the lack of conjugase in kernicterus of the newborn, may be facilitated by the administration of sulphamides. These are adsorbed even more intensively by the albumin than is the bilirubin and take the place of the latter on the carrier protein. Here the bilirubin is bound to the secondary extravascular surface in basal ganglions, as well as on other parts of the organism. Similar mechanisms are also apparent in the pathogenesis of Wilson's disease, of siderosis and so on.

Due to the action of lipoprotein lipases the absorbed lipids follow a definite pathway through the various plasma lipoprotein fractions—the fatty acids released being bound by albumin[2].

According to Leszler's investigations[3], in which he followed the intravenous administration of phenolphthalein, indigo carmine and also tripaflavin, up to their elimination, a considerable lowering of the serum cholesterol-level may be observed. This phenomenon can be explained by the competition which exists between the dye and the cholesterol for the transport surface of the albumin which is available. Frederickson[4] demonstrated that consumption of carbohydrates leads to a lowering of the free fatty acid-content of the plasma, as well as a lowering of the turnover of chylomicrons. The effect on the plasma glycoproteins brought about by changes in lipoprotein-level has yet to be elucidated. Similarly, few data are available regarding the pathological changes due to the correlations existing between the glyco- and lipo-proteins.

In the course of investigating alimentary lipaemia, we studied the simultaneous changes in the capacity of albumins to bind Congo red, as well as those occurring in the lipo- and glyco-proteins, both in healthy and in atherosclerotic individuals.

Ten patients suffering from atherosclerosis were examined, as well as ten healthy students, who in the morning of the test had ingested 50 g of butter. Beforehand, and 4, 6 and 7 h following the consumption of the fat, we determined: (1) the Congo red-binding capacity of albumin (the Congo red was precipitated through a saturated sodium chloride solution, while the albumin-bound dye remained in the solution. After standing for 24 h, the solution was filtered and the extinction of the filtrate was determined)[5]; (2) the total lipids present using Swahn's method; (3) the paper electrophoretic patterns of the lipoprotein fractions; (4) the total neutral glycoproteins according to our own method[6]; and (5) the paper electrophoretic patterns of the glycoprotein fractions. Our results are shown in Table 1.

In atherosclerotics the alimentary hyperlipaemia is associated with a marked decrease in total neutral glycoproteins—a phenomenon which does not occur in healthy individuals. The neutral glucide content of albumin, as well as that of β globulin, is decreased, while that of α-1, α-2 and γ globulins is increased. These modifications indicate a tendency towards a slower return to normal in the case of atherosclerotics than in healthy individuals. Measurements of the capacity of albumins to bind Congo red in healthy individuals failed to show any significant modifications; in atherosclerotics this capacity decreased 6 and 7 h after the ingestion of the fat. We believe that we are here confronted with a decrease in the transport capacity of albumin and β-globulins. A fact in favour of this mechanism is that the decreased Congo red-binding capacity, arising as a result of alimentary lipaemia, is similar to that brought about *in vitro* by treatment with sulphamide and barbital sodium, as well as that in the serum of patients suffering from epidemic hepatitis.

On the basis of the foregoing, the following working hypothesis can be formulated. In atherosclerosis we may note the appearance of various causes capable of modifying the transport medium. Apart from a decrease of the lipoprotein lipase and a lowering of the transport capacity of proteins caused by a disproteinaemia, the depolymerization of the fundamental substance may lead to the introduction into the blood stream of a large amount of glucidic fragments. This may lead to competition for the transport surfaces, thus facilitating the de-adsorption and elimination from the circulating blood of the less strongly bound lipids. Our investigations confirm the validity of the foregoing suppositions regarding the nature of this pathogenetic mechanism. Undoubtedly, we have to deal with a decrease of the transport capacity of albumin and β-globulins, as compared with the available lipids and glucides. In the latter case—irrespective of the complex and multilateral origin of these modifications—

it can be stated that the decrease in the transport capacity facilitates the de-adsorption of lipids, thus facilitating their elimination from the blood. As a result of the continuous increase in the lipids available to the tissues, after a certain period, a shift in the site of fixation from the carrier protein towards the secondary surfaces of the endothelium into the vascular walls can be noted. If the pathogenetic picture of atherosclerosis with the multiple role of the modifications affecting the transport medium could be completed, it would undoubtedly contribute to a better understanding of this disease and open new vistas in its therapy. This could be achieved by increasing the blood transport capacity by way of drugs and through the prevention of the excessive loading of the transport capacity of plasma proteins.

Testicular Calcinosis in Domestic Ruminants

CALCIFICATION in the testes of bulls has been the subject of a few reports over several decades[1–3]. Accounts of the condition have been mainly concerned with its incidence in surveys and theories on its aetiology. It is established now that the condition is usually bilateral in its occurrence, varies in degree, and is by no means rare. There is general support for a hypothesis that semen statis is a fundamental factor in the development of the condition[4,5]. Doubt has been cast on the reproductive significance of such calcification with the statement that, *per se*, it does not necessarily indicate infertility[3]. The association between the condition and fertility has not otherwise been closely considered.

We have investigated calcinosis (using Selye's terminology[6]) in the testes of domestic ruminants by assessment of gross calcinosis on cut surfaces of affected testes from sheep, goats and bulls with known breeding histories and by occasional histo-pathological examination of affected testes. Our aim has been to obtain clarification on (*a*) the degree of association between testicular calcinosis, sperm abnormalities, and infertility; (*b*) the sequence of events in the tubular tissue leading to calcium deposition; (*c*) the consistent and several characteristics of the condition in cattle, goats and sheep. The broad results of these observations to date are summarized as follows.

Testicular calcinosis occurred in association with lesions in the epididymis or adjacent testicular parenchyma. Masses of dead spermatozoa gathered in related collecting tubules and occluded them; such tubules ruptured with spermatocoele and granuloma formation as a common result. Seminiferous tubules in affected testes showed atrophic change and testicular shrinkage was sometimes apparent. The calcification process appears to become established by way of saponification, with granule formation in sperm masses.

Generalized testicular calcinosis was associated with reduction in semen qualities and hence with varying degrees of infertility. Advancing degrees of gross calcification progressed through oligospermia, of the order of 4,000 sperms per ml., to azoospermia.

Intermediate degrees of bilateral calcification were associated with some fluctuations in the quality of ejaculates. Fair to poor motility of spermatozoa was a fairly constant feature on microscopic examination of warmed samples of whole semen. Abnormal morphology varied, but consisted chiefly of defects of the neck and tail, for example, separated heads and tails, and bent tails.

Subjects with unilateral calcinosis of an intermediate degree gave semen samples which varied considerably, particularly with regard to the percentage of abnormal sperm forms. Motility was usually poor, seldom good. Advanced cases were sterile whereas intermediate cases showed varying degrees of fertility about or below the lower level of common fertilizing rates (for example, 60 per cent lambing rate to a Suffolk ram with unilateral calcinosis to an intermediate degree). Some very mildly calcified testes have been found in subjects with histories of average fertility, but no reputedly highly fertile sire has been found with gross testicular calcinosis.

No true age incidence is apparent; advanced cases have been found in young subjects.

Compared with the widely confirmed incidence of up to 30 per cent in bulls, the approximate incidence of significant calcification appears to be relatively low in sheep (3 per cent) but high in goats (up to 40 per cent), in which latter species the condition, in its advanced form, obviously contributes to the common sterility of males.

RADIOBIOLOGY

Stable Bromine and Activation Analysis in Protein Tracer Studies

ALTHOUGH the judicious use of radioisotopes such as iodine-131 and iodine-125 for tracing proteins in metabolic studies in man may result in very little iatrogenic exposure of the subject to radioactivity, a general method for labelling such proteins which would not expose the patient to even this small amount of radiation would be preferable, especially in infants and pregnant women. In the present investigation, the feasibility of using neutron activation in the study of the metabolism of proteins labelled with stable bromine, bromine-79 and bromine-81 was explored the latter isotopes have suitable cross-sections for thermal neutron capture, bromine-79 being activated to bromine-80 (half-life of 4·4 h) and bromine-81 being activated to bromine-82 (half-life of 36 h) (ref. 1).

Human serum albumin and human serum IgG were labelled with stable bromide which contained equal parts of bromine-79 and bromine-81. 1·0 ml. of 0·1 N hydrochloric acid was added to 4 μmoles of potassium bromide in 0·05 ml. water; the bromide was oxidized to bromine with 0·05 ml. of 12·5 per cent sodium hypochlorite solu-

tion, and this was added promptly to 1 μmole of the protein dissolved in 2 ml. of 0·1 M sodium bicarbonate buffer, *p*H 9·4, and kept in an ice-bath. After 5 min, the brominated proteins were passed through a column of Dowex 1 and then dialysed for 24–48 h against several changes of 0·1 N sodium chloride. In an identical manner, additional aliquots of albumin and γ-globulin were radio-brominated using bromine-82 labelled sodium bromide with stable potassium bromide as a carrier; more than 98 per cent of the radioactivity in the latter protein preparations was precipitable with 10 per cent trichloro-acetic acid (TCA) and there was less than 1 atom of bromine per molecule of protein. Human serum albumin and IgG were also labelled with iodine-125 using a nitrous acid method[2].

Adult albino female mice were injected intravenously with 0·025 μmoles of the stable brominated proteins in 0·1 ml. of 0·15 M sodium chloride, and the disappearance of the proteins was followed by obtaining serum samples at regular intervals beginning 5 min after the injection. The serum samples obtained from a group of mice at a given time after injection were pooled, and the serum pools were dialysed against several changes of 1 N ammonium hydroxide for 3–4 days to remove as much Na^+, K^+, Cl^-, Br^- and brominated protein degradation products as possible to avoid radio-activation of these elements. 0·5-ml. portions of dialysed sera were placed in the centre of 3 cm lengths of polyethylene tubing, 5 mm in internal diameter, and the samples were dried at 70° C for 4 h (ref. 3). Both ends of the tubing were sealed with heat, the tubes were placed in a nylon container and then exposed for 24 h in the Brookhaven graphite-moderated research reactor in a flux of approximately 9×10^{12} thermal neutrons/cm²/sec. After irradiation, the tubes were left behind lead shielding for 24–48 h to permit decay of short-lived activation products after this period; both ends of the tubes were cut off, and the irradiated samples were recovered by boiling the tubing in 5 N sodium hydroxide for several minutes followed by two washings in distilled water. The samples were then assayed in a 400 channel scintillation spectrometer with a 3 in. sodium iodide crystal: the energy spectrum of bromine 82 was apparent, but sodium-24 was found to be present in variable concentrations in most of the samples. The sodium-24 spectrum was subtracted from the energy spectrum of the sample and the amount of bromine-82 present was estimated from the remaining gamma emission having an energy peak at 0·787 MeV. The amounts of bromine-82 in the sera were plotted against time after injection, the amount found in the sera obtained 5 min after injection being taken as 100 per cent. Using this method, the half-life of stable brominated human albumin in mice was found to be 18·5 h (Fig. 1) and that of stable brominated human IgG was 2·5 days (Fig. 2).

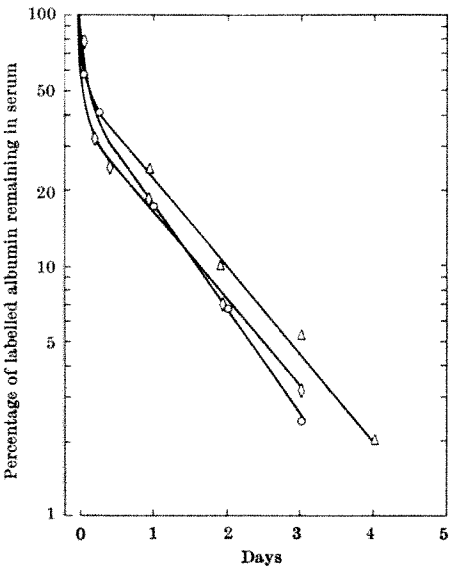

Fig. 1. Disappearance of intravenously injected human albumin-^{125}I (△), albumin-^{82}Br (◇), and stable brominated albumin (○) from the serum of the mouse. Stable brominated albumin was detected by neutron activation analysis

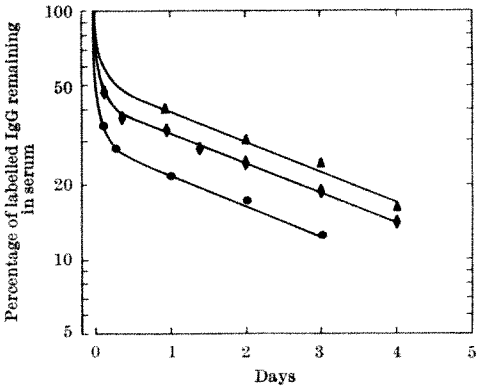

Fig. 2. Disappearance of intravenously injected human IgG-^{125}I (▲), IgG-^{82}Br (◆), and stable brominated IgG (●) from the serum of the mouse. Stable brominated IgG was detected by neutron activation analysis

To compare the turnover of these stable brominated proteins with that of radio-isotopically labelled proteins, albumin labelled with bromine-82, albumin labelled with iodine-125, IgG labelled with bromine-82, and IgG labelled with iodine-125 were injected intravenously into separate groups of mice. Sera were obtained from the mice at regular intervals and aliquots of the sera were dialysed against 0·1 N sodium chloride; after dialysis, 99 per cent of the radioactivity in each serum sample could be precipitated with TCA. The half-life of albumin-^{82}Br was 18 h and that of albumin-^{125}I was 19 h (Fig. 1); IgG-^{82}Br had a half-life of 2·4 days and that for IgG-^{125}I was 2·5 days (Fig. 2).

Thus, the turnover of the stable brominated plasma proteins in mice as assayed by neutron activation appeared to be similar to the turnover of their radio-brominated and their radio-iodinated analogues. The theoretical limit of detection under the conditions of irradiation and detection used in this study was calculated to be 1×10^{-11} moles of bromine, but the actual limit of detection under these conditions was found to be 1×10^{-9} moles of bromine. Simply by lengthening the time of irradiation and utilizing samples of greater size, the smallest amount of bromine detectable by this method is readily decreased more than tenfold. This investigation supports the feasibility of utilizing stable brominated proteins and neutron activation analysis for the study of plasma protein metabolism where exposure of the subject to even small amounts of radiation is undesirable.

This investigation was supported by grants from the U.S. Atomic Energy Commission, the National Institutes of Health, U.S. Public Health Service, and the Ronni Miller Fund of the Children's Hospital of Pittsburgh.

BIOLOGY

Concentration of Entries in Binary Arrays

NUMERICAL methods for the classification of elements into sets commonly begin with an assortment of individuals defined by the possession or non-possession of a number of attributes, and seek to provide final sets of highly similar individuals[1,2]. The attribute-groups which form the basis of such a classification may also be of interest, in which case the system may be transposed and the attributes classified into groups by reference to the individuals[3]. Finally, attempts have been made[4] to extract 'noda', simultaneously defined by a final set of individuals and by a final set of attributes. Existing methods for the extraction of such noda sub-divide individuals and attributes independently and collate the results by reference to a 'two-way table'; but such methods do not provide the most efficient concentration of positive entries. It should in principle be possible to obtain each block substantially independently of the others, concentrating its entries by reference to such individuals and attributes as are involved in it; but, except in the trivial case of the 'black-and-white' table, it is not to be expected that the blocks will then dispose themselves conveniently within the cells of a conventional two-way table. Some may be expected to do so, but some will almost certainly transgress cell-boundaries and/or occupy only part of the fixed cells.

The situation can be improved if, at any stage, the incipient divisions in the two directions can be made comparable, so that division can be effected of either individuals or attributes, whichever gives the greater concentration. This would be possible with existing systems if a probabilistic parameter were in use, so that the two probabilities could be directly compared; but the computation would be extremely heavy, and the purpose of this communication is to suggest an altogether simpler strategy which will serve a similar purpose. Suppose a data-matrix to be divided into two groups of A and α individuals specified by two groups of B and β attributes; the table is now divided into four cells with possible maximum entries of AB, αB, $A\beta$ and $\alpha\beta$; let the actual positive entries be a, b, c and d respectively; and write $N=(A+\alpha)(B+\beta)$ and $n=(a+b+c+d)$. Although we now have the form of a 2×2 table, the usual null hypothesis based on marginal totals is inapplicable, since it may require a cell to contain more unities than there are spaces available (for example, that $a>AB$). We therefore state a new null hypothesis. The proportion of unities to total spaces is n/N: call this k. The hypothesis states that this proportion occurs in each of the four cells, that is, that the unities are disposed in proportion to the spaces available. For the first cell the expected number of unities is ABk, and of zeros $AB(1-k)$; the corresponding observed numbers are a and $(AB-a)$. It is easily shown that the contribution of this cell to a χ^2 is

$$\frac{(a-ABk)^2}{ABk(1-k)}$$

and the remaining three contributions can be written down by symmetry. Since A, B, α and β are given, only one parameter—n—is used in calculating the expectations, and the resulting χ^2 has three degrees of freedom. Mather[5] has shown how such a χ^2 can be partitioned into three additive components, each with one degree of freedom; using his methods we obtain the partition:

For the A/α division $\dfrac{\{(a+c)\alpha-(b+d)A\}^2}{k(1-k)A\alpha N}$

For the B/β division $\dfrac{\{(a+b)\beta-(c+d)B\}^2}{k(1-k)B\beta N}$

For the interaction $\dfrac{(a\alpha\beta-bA\beta-c\alpha B+dAB)^2}{k(1-k)A\alpha B\beta N}$

We note five properties of interest: (i) the maximum value of the total χ^2 is N, achieved by any division of the table into completely full and completely empty cells; (ii) empirical tests suggest that the direct comparison of the A/α and B/β divisions is more profitable than consideration of either the total χ^2 or the interaction; (iii) k must be calculated anew at each successive division, or else the χ^2 will have four degrees of freedom and the rationale of the partition will fail; (iv) χ^2 components for successive divisions are not monotonic, and do not define a stopping rule, which must be based on density and overall content of cells; (v) the system can be immediately generalized to arrays of more than two dimensions.

In any divisive system, since consideration of all dichotomous choices is normally impracticable, a restricted set of divisions must be designated. We have adopted the usual divisive strategy of considering only monothetic splits; but as a test we have enumerated all 961 divisions of a 6×6 table, and have been reassured to find that the highest contributions in both directions were from monothetic divisions. The method has been applied to a 15×27 set of ecological data of 20 per cent overall density, and produced five cells, which had a mean density of 81 per cent and accounted for 70 per cent of the positive entries; it is noteworthy that these cells cannot be contained within a conventional two-way table. This very satisfactory degree of concentration suggests to us that the method will find particular value in the analysis of tables which, by conventional methods, concentrate at an unacceptably low level. It is being tested on larger-scale ecological data, and the results will be submitted for publication to an ecological journal in due course.

The Nature of Pseudovacuoles in Cyanophyceae

THE nature of the pseudovacuoles, or gas vacuoles, which occur in bacteria and Cyanophyceae, is still enigmatic, although a number of reviews have been devoted to them.

The opinion which still prevails is that put forward by Fritsch[1]. After discussing the various observations and opinions with respect to Cyanophyceae he concluded that "the vacuoles develop at the bottom under anaerobic conditions (by a kind of gas-producing fermentation), and that as a result of the buoyancy thus acquired, the forms in question float to the surface". He doubted "whether material possessed of pseudovacuoles is actually in a healthy condition and whether cell-division continues".

Observations on a strain of *Oscillatoria agardhii*—a typical plankton—in axenic culture[2] (the first in which pseudovacuoles were isolated bacteria-free) showed that this view did not hold true for all cases. *O. agardhii* is strictly photo-autotrophic and damaged by organic nutrients—even by glucose at concentrations as low as 0·01 per cent. This in itself does not exclude the possibility of the gas being produced by a kind of fermentation, but at least it renders it impossible to prove.

It was possible to show that in this alga, pseudovacuoles are not simply gas-bubbles in a colloidal protoplasmic matrix but are instead cell-organelles of definite shape. They are elongated and multiply by fission. When centrifuged they decrease considerably in number, but after a few hours they gradually reappear in similar shape and arrangement as before.

These structures can be found during healthy propagation in all trichomes of the algae provided they remain floating, in raw and in pure cultures, and also in *Aphanizomenon gracile*. They are also present when cultures are kept under continuous illumination, and thus deficiency in oxygen is out of the question.

The possibility has to be considered that the pseudovacuoles, which no doubt keep the trichomes afloat, are caused by true inner exudation of gas.

Histochemical Studies on the Rediae and Cercariae of *Echinoparyphium recurvatum* Linstow

ALTHOUGH information is available on the effects of trematode larvae on the gonads and digestive diverticulum of their molluscan hosts[1–3], surprisingly little is known regarding the feeding and enzyme systems of larval trematodes.

The preliminary results of this investigation deal with the acid and alkaline phosphatases and non-specific esterases of the redia of *Echinoparyphium recurvatum* occurring within the host snail *Lymnaea pereger*. Histochemical tests for alkaline and acid phosphatase were carried out on both fixed (10 per cent neutral formalin) and unfixed cryostat sections of rediae removed from the host tissues and supported in mammalian liver, according to the methods of Gomori as outlined by Pearse[4]. Incubation times: alkaline phosphatase 24 h at 37° C, and acid phosphatase 5·5 h at 37° C. Inhibitors used as controls were 10^{-2} M potassium cyanide and 10^{-2} M sodium fluoride and, made up in water, these were found to be effective. Non-specific esterases were demonstrated by the indoxyl-acetate method after Pearse[4].

A weak acid-phosphatase activity was seen in the cuticle of the redia and a stronger reaction in the cuticle and suckers of developing cercariae. The caecal walls and contents together with the oral lips of the pharynx were strongly acid phosphatase positive. Alkaline phosphatase did not appear to be present in the cuticle wall of the redia but was seen in the suckers and cuticle of developing cercariae which is probably associated with cellular differentiation. The caecum, caecal contents and the oral lips of the pharynx (Figs. 1 and 2) were strongly positive. The walls of the lateral excretory ducts (Fig. 3) and bladder were also strongly active.

Erasmus[5] has shown alkaline phosphatase activity in the cuticle of the sporocyst of *Cercaria X* Baylis. Dusanic[6] also demonstrated alkaline phosphatase in the cuticle of the sporocyst of *Schistosoma mansoni*. Cheng[7] investigated the distribution of phosphatases in the redia of *Echinoparyphium* sp. where it was seen to differ somewhat from that in redia of our specimens. Acid phosphatase was not demonstrated by Cheng except in the caecal contents, while alkaline phosphatase was seen in the cuticle. A similar distribution of alkaline phosphatase was seen elsewhere although not in the pharynx.

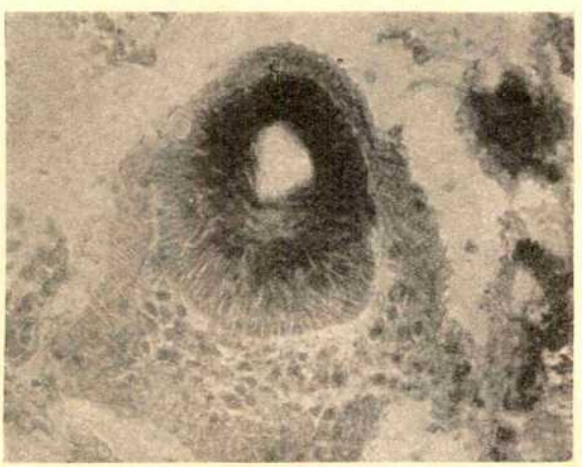

Fig. 1. Longitudinal section of pharynx of redia showing alkaline phosphatase activity in the walls lining its lumen. (× *c.* 600)

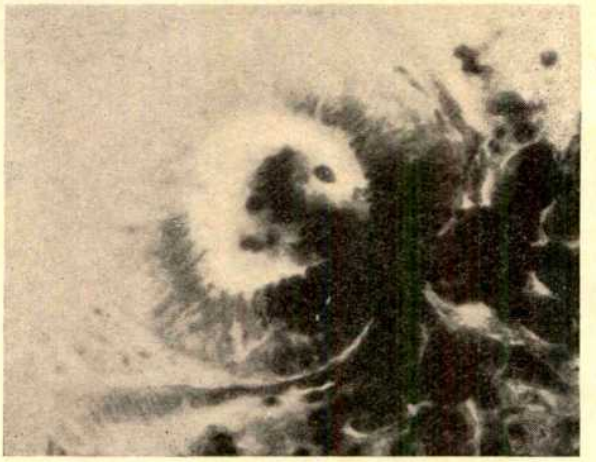

Fig. 2. Longitudinal section of pharynx of redia ingesting liver cells showing alkaline phosphatase activity (dark regions) in the oral lips and surrounding tissues. (× *c.* 600)

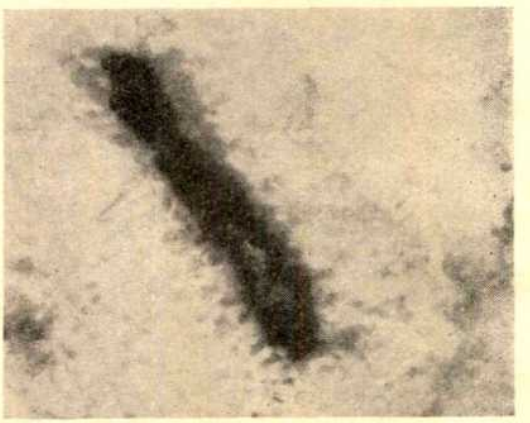

Fig. 3. Longitudinal section of primary excretory duct of a cercaria showing alkaline phosphatase activity in its walls. (× *c.* 1,200)

The biological role of the non-specific phosphatases is still not understood and the position is reviewed by Nimmo-Smith and Standen[8]. They suggest that the cuticular phosphatases in the adult worms of *Schistosoma mansoni* may be functioning in the uptake of nutrients. Cheng suggests that the alkaline phosphatase in the redial wall of *Echinoparyphium* sp. may be functioning either for the phosphorylation of substances for passage through the body wall[9–13] or in the hydrolytic catabolism of glycogen in the surrounding host tissues[1–3,14]. The pharynx in *E. recurvatum* may be involved in the secretion of phosphatases (Erasmus[12,13] demonstrated that cuticular phosphatases in *Moniezia expansa* can hydrolyse substances outside or in the immediate environment). There certainly appears to be a zone of high phosphatase activity at the oral lips (Fig. 1) and in the immediate vicinity of the pharynx during ingestion of supporting liver tissue (Fig. 2). It seems likely that the presence of phosphatases in the pharynx caecal walls and cuticle is correlated with absorption of nutrients, if this is in fact their function. Cheng[14] suggests that indigestible debris along with host enzymes may be regurgitated from the redial caecum, and that these enzymes account for any local histolysis.

Coil[15] demonstrated alkaline phosphatase in the excretory system of trematode cercariae, particularly in the tubules leading from the flame cells. Alkaline phosphatase activity has been shown in the lateral excretory ducts of the cercariae of *Echinoparyphium recurvatum* which corresponds with the distribution found by Cheng, and also in the walls of the bladder. Roche[16] points out that the proximal renal tubules of vertebrate kidney are also highly active for alkaline phosphatase. It seems possible that a role of resorption of nutrients such as glucose may be the function of alkaline phosphatase in the excretory system of trematodes.

A strong activity of non-specific esterase was found in the oral lips of the pharynx, and to a lesser degree in the cuticle of the redia. Activity in unidentified tissues was also seen in developing cercariae. The significance of this enzyme activity is not as yet clear. The presence of fats in sporocyst and redial stages has been described by Ginetzinskaya[17], and it is possible that the esterase activity described here may be associated with some aspect of fat metabolism within the redia.

This work was carried out in the Department of Zoology, University College of South Wales and Monmouthshire, Cardiff.

MICROBIOLOGY

Role of Carbon Dioxide and Acetate in Biosynthesis by Sulphate-reducing Bacteria

SULPHATE reduction by bacteria is one of the most important biogeochemical processes for which microorganisms are responsible. Sulphate-reducing bacteria obtain energy for biosynthesis from the very small amount released in the reduction of SO_4-ions with the participation of easily activated hydrogen of certain organic compounds and with hydrogen gas. Previous work[1,2] and my recent experiments have shown that the principal sulphate reducer, *Desulphovibrio desulphuricans*, in pure culture, can only use for this purpose the hydrogen of formate, isobutanol, lactate, pyruvate and ethanol, which are oxidized during the reduction of sulphate to carbon dioxide, butyrate and acetate as the case may be. Among these substances, only the last-mentioned three suffice as sole sources of both energy and carbon for growth. The others are used merely as sources of energy; carbon for biosynthesis must be supplied in this case by the addition of yeast extract[3,4].

Such a limited number of possible energy and carbon sources for bacterial sulphate reduction does not correspond with the very wide distribution of this process in Nature. The experiments described here provide some explanation for this apparent contradiction. The strain of *D. desulphuricans* used was isolated from the underground water of an oilfield. During attempts to grow this strain with formate or hydrogen gas as sole energy source I found that normal growth is dependent on the presence of a small amount of acetate in the medium. Stimulation of growth begins with the addition of 10 mg/l. of sodium acetate and 40 mg/l. gives optimum growth and sulphide production. As the acetate is not oxidized by this bacterium it could only serve as a source of carbon for biosynthesis. In Table 1 are presented data demonstrating almost complete removal of added acetate from the medium in the culture of *D. desulphuricans* grown in the presence of formate.

Table 1. REMOVAL OF LABELLED ACETATE FROM THE MEDIUM BY CELLS OF *D. desulphuricans* DEVELOPING IN FORMATE MEDIUM*

Radioactivity of sodium acetate added (15 mg/l.) (c.p.m./l.)	Radioactivity of bacteria (c.p.m./l.)	
	Count of bacteria sedimented on 'Millipore' filter	Count of bacterial carbon recovered as barium carbonate
$4{\cdot}25 \times 10^5$	$3{\cdot}88 \times 10^5$	$3{\cdot}43 \times 10^5$

* Medium: 3 g potassium monohydrogen phosphate, 1 g sodium dihydrogen phosphate, 0·2 g ammonium chloride, 0·1 g magnesium sulphate, 1·5 g sodium sulphate, 6 g sodium formate and 1 l. of water.

Another source of carbon for *D. desulphuricans* which may provide about 30 per cent of the carbon needed for biosynthesis is exogenous carbon dioxide. This was shown by my previous experiments with *D. desulphuricans* isolated from reservoir mud[5] and grown in a lactate medium. To show the part played by carbon dioxide and acetate as carbon sources experiments were carried out using labelled compounds: $H^{14}COONa$, $H^{14}CO_3$, $^{14}CH_3-{}^{14}COONa$.

The cultures were grown in mineral medium with the addition of one of the labelled compounds. The specific activities were measured of carbon of the supplied compounds at the beginning and end of the experiment and of carbon of the bacterial cell material. In order to prevent any decrease of the specific activity of the labelled carbon dioxide or acetate with unlabelled molecules formed by bacterial metabolism, a high concentration of the former (6–8 g/l.) was supplied in the medium. The proportion of the cell carbon originating from the labelled compound was calculated as a percentage[6] from the values of specific activity.

Table 2. ACETATE AND CARBON DIOXIDE IN THE BIOSYNTHESIS OF *D. desulphuricans*

Source of energy		Additional sources of carbon for cell synthesis				Percentage of cell carbon derived from the labelled substance
		^{14}C-labelled		Unlabelled		
Substance	Conc. g/l.	Substance	Conc. (mg/l.)	Substance	Conc. (mg/l.)	
Hydrogen gas	Gas phase	$NaH^{14}CO_3$	1,000	Na-acetate	5	48·0
,,	Gas-phase	,,	1,000	,,	30	31·7
Na-formate	6	,,	5,000	,,	20	31·5
,,	6	,,	5,000	Na-acetate + peptone	20 + 200	30·6
Ethanol	3	,,	1,000	—	—	31·4
Na-lactate	4	,,	5,000	—	—	29·9
Hydrogen gas	Gas phase	$^{14}CH_3$-$^{14}COONa$	20	$NaHCO_3$	1,000	66·8
Na-formate	6	,,	40	,,	1 000	70·1
,,	6	,,	100	$NaHCO_3$ + yeast extract	1,000 + 200	30·2
,,	6	,,	20	Glucose	100	31·6
,,	6	,,	40	Isobutanol	200	32·3
Na-formate-^{14}C	6	—		Na-acetate	40	2·4
Ethanol	3	$^{14}CH_3$—$^{14}COONa$	8,000	—	—	68·5

The results show (Table 2) that *D. desulphuricans* is not capable of true autotrophy—as was previously pointed out by Postgate[3] and Mechalas and Rittenberg[4]. But, according to these authors, only 5–10 per cent of the cell carbon originates from carbon dioxide and the rest from the yeast extract added. The strain that I used assimilated 30–50 per cent of the carbon of the exogenous carbon dioxide when grown in an atmosphere of hydrogen with trace amounts of acetate. Without the latter the growth of cultures inoculated with washed cells was marginal. If bacteria were grown in the presence of formate or in more complex lactate or ethanol medium, carbon dioxide assimilation was consistently equal to 30 per cent. Even the addition of yeast extract and peptone did not lower this value. This phenomenon definitely distinguishes *D. desulphuricans* from the various heterotrophs and facultative autotrophs which show decreased carbon dioxide utilization in the presence of complex organic matter[6].

Experiments with labelled acetate have demonstrated the possibility of *D. desulphuricans* synthesizing all its cell material from carbon dioxide and acetate carbon, assimilated in the proportion 1:1, resulting in a ratio of C_1 to C_2 of 1:2. In the presence of C_3-, C_4- or C_6- compounds the proportion of cell organic matter originating from acetate is lowered from 68–70 per cent to 32–40 per cent. These data show the possibility of partial assimilation of other carbon sources including glucose, isobutanol, yeast extract (but not peptone) for biosynthesis, together with acetate.

When *D. desulphuricans* is grown in media rich in hydrogen gas, formate or ethanol its energy-yielding metabolism appears to be spatially separated from cell synthesis: connexion occurs only through the bound energy and hydrogen transfer. The carbon dioxide and acetate formed inside the cells during the oxidation of formate or ethanol are not directly involved in the synthesis of cell material (Table 2). Utilization of these compounds proceeds only from the medium.

The cells grown in ^{14}C-formate medium are practically unlabelled. Cells grown on unlabelled ethanol in the presence of a large amount of ^{14}C-acetate become labelled at a level corresponding to the utilization of 70 per cent of the external labelled acetate (the remaining 30 per cent of cell carbon is derived from carbon dioxide).

The results given here show that the sulphate reducers can normally grow using the simple basic products of the anaerobic decay of organic material: hydrogen gas formate and acetate, without any lactate and yeast extract. This perhaps explains the wide distribution and great intensity of the process of carbon dioxide reduction in natural conditions.

The capacity of *D. desulphuricans* to use the energy of hydrogen and formate oxidation for the biosynthesis of cell material by C_1+C_2 reaction is similar to that of some formate-oxidizing and purple bacteria[7].

ENTOMOLOGY

Sequestration of Protein by the Fat Body of an Insect

THE fat body in an insect commonly contains a single cell type which is functionally diverse. At various times it stores and mobilizes fat, protein and glycogen which it may have synthesized or sequestered. In general the fat body becomes filled with reserves as metamorphosis approaches[1]. Larvae of *Aëdes* fed on casein build up reserves of protein granules in the fat body[2], and in *Drosophila* larvae, protein granules are induced to form in the middle of the third stadium by a hormone from the ring gland[3]. In *Calpodes* larvae the protein granules are probably translocated endocuticle. They arise suddenly within the Golgi vesicles 30–35 h before pupation, at a time when the thick larval endocuticle is being resorbed by the moulting fluid. At about 10 h before pupation other granules containing both protein and ribosomes arise from the isolation of endoplasmic reticulum in cytolysomes[4]. Although the formation and occurrence of protein granules in the fat body are well documented, there is little information on the origin of the protein.

In silkworm (*Bombyx*) larvae the fat body synthesizes protein[5] which appears in the blood. It has generally been assumed that the protein granules are also synthesized by the fat body. For example, Butterworth *et al.*[3] directed attention to the enlarged vesiculate nucleoli, typical of cells synthesizing protein, which occur at the time the protein granules begin to form in the fat body of *Drosophila*. Also, mitochondria are reported to synthesize protein[6], and according to Gaudecker[7] the protein granules arise from mitochondria in *Drosophila*. The question arises whether or not the protein granules are synthesized from amino-acids *in situ* or are synthesized elsewhere, merely to be sequestered by the fat body.

The following experiments show that, in *Calpodes*, the fat body sequesters blood proteins to form the granules and synthesizes rather little of them. If the fat body synthesizes the protein, then if we inject tritiated amino-acids into the haemocoel we should expect: (1) that the incorporation would be high in the fat body at the time of granule formation relative to other times, and (2) that the incorporation would be higher in at least some of the granules than in the rest of the fat body cell. To test this, a series of twenty-eight larvae were injected with ^3H-tyrosine (dose 20 μc./g) for a 2-h period of incorporation at various stages in the fifth and pupal stadia. Autoradiographs were prepared and grain counts made. Incorporation into the fat body was no higher at the time of protein granule formation than at other times in the stadium. In contrast, there was considerable incorporation into the epidermis when the protein granules were forming and endocuticle was being resorbed. The moulting fluid contains proteolytic enzymes[8] and presumably the cuticular protein is taken up by the epidermis as amino-acids. If the epidermis synthesizes protein from the products of digestion of the larval cuticle, we should expect a high rate of incorporation at this time (Table 1). This would not be true if it were merely passing the amino-acids from the digested cuticle into the blood. A comparison was also made between the incorporation into the granules and into the rest of the fat body cell (excluding the large area occupied by lipid from the count). The granules do not have any higher incorporation than the rest of the cell and no granules seem strongly labelled (Table 1). The incorporation into the protein granules themselves was remarkably low at all stages of their formation. Under comparable conditions, incorporation into the pupal cuticle is four to six times as high (Table 1). Most of the granules appear during a period of about 12 h, and the rate of protein deposition is probably no lower than the rate of deposition in the cuticle. Similar results were obtained after the incorporation of ^3H-leucine. The low incorporation in the granules is not due to too short a period for uptake and synthesis *in situ*. The incorporation only increases slightly as the period is lengthened to 16 h, spanning the greater part of the time during which the granules are forming (Table 2). The results make it unlikely that the fat body synthesizes much of the protein in the granules which form there. We there-

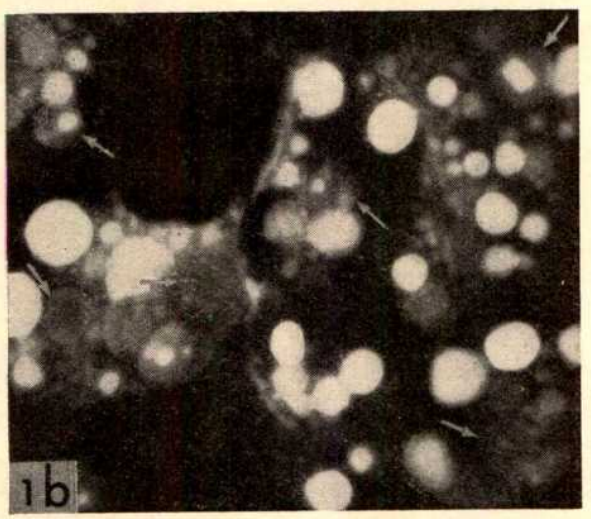

Fig. 1. The fat body of *Calpodes ethlius* during the formation of the protein granules 4 h after the injection of peroxidase (1 mg/g) into the haemocoel. Frozen sections were treated with benzidine to show the location of peroxidase. *a*, Viewed by transmitted light the peroxidase containing granules appear dark; *b*, the same field viewed by fluorescence shows many other protein granules or parts of granules not containing peroxidase which fluoresce brightly. Arrows mark some of the peroxidase containing granules (×720)

fore explored the alternative hypothesis that the fat body sequesters protein which it does not synthesize.

If the fat body sequesters proteins from the blood, it should be possible to trace the passage of a foreign, recognizable protein into the granules. Horse radish peroxidase was chosen for this purpose[9]. The enzyme (1 mg in 0·1 ml. Ringer's solution) was injected into larvae when the protein granules were forming. Four hours later the larvae were fixed in cold glutaraldehyde and frozen sections prepared. The sites of peroxidase activity were visualized by the blue or brown colour developed after treatment with alcoholic benzidine hydrochloride. When viewed by transmitted light some of the granules were entirely coloured, others were colourless and some may have resulted from the fusion of smaller granules of both sorts (Fig. 1*a*). The granules are easily distinguished by fluorescence microscopy. The natural granules fluoresce yellow when excited by ultra-violet light, but this is masked in granules containing peroxidase after the benzidine reaction (Fig. 1*b*). We may conclude that the fat body sequesters proteins from the blood to form the protein storage granules.

VIROLOGY

Change in Chang Liver Cells from Virus Susceptibility to Resistance mediated by Persistent Infection with Echovirus Type 9

CERTAIN mutants of echovirus type 9 are able to destroy a variety of stable epithelial cell lines—Chang liver, *KB* and *FL*. This genetic character, designated by us *cha*$^+$, has been used to differentiate the various mutants of echovirus type 9, some occurring in the *cha*$^+$ and others in the *cha*$^-$ forms[1,2]. A persistent infection may be established in vigorously growing Chang liver cells when a low virus inoculum of a *cha*$^+$ mutant is used. This infection is characterized by virus multiplication to high titre in the absence of microscopically visible cellular damage. Such a virus carrier state can be maintained for long periods of time by regular changes of growth medium and passage of the cells, and may finally result in spontaneous cure and total loss of susceptibility of the cells to homologous virus challenge. This communication deals with certain aspects of this virus-cell system.

From the Quigley strain[3] of echovirus type 9, a mutant was obtained through the action of nitrous acid[4]. An important characteristic of this mutant is its ability to produce plaques on both Chang liver and primary monkey kidney cells, which was useful in the assay of the virus. This mutant has been used to initiate a persistent infection in Chang liver cells using a low virus inoculum, of approximately 10^3 P.F.U. per 3×10^6 cells, and maintaining the cultures in a cell growth medium. The growth medium consisted of Earle's balanced salt solution, lactalbumin hydrolysate 0·5 per cent, 0·01 per cent yeast extract and 15 per cent calf serum. The virus-carrier state was initiated and maintained in Chang liver cells grown in this medium in milk dilution bottles. The number of cells per bottle varied between 2×10^6 and 5×10^6. Virus titrations were carried out in primary monkey kidney cell monolayers, in tubes or plates.

After inoculation and an adsorption period of 1 h, virus could not be detected in the supernatant fluid of the cell cultures when tested on three occasions during the first 5 days (Fig. 1). At the beginning of the second week, the virus titre in the supernatant fluid was $10^{4.5}$ P.F.U./ml. Virus titres were afterwards maintained at the level of $\geqslant10^{5.5}$ P.F.U./ml. for a number of weeks. Medium was

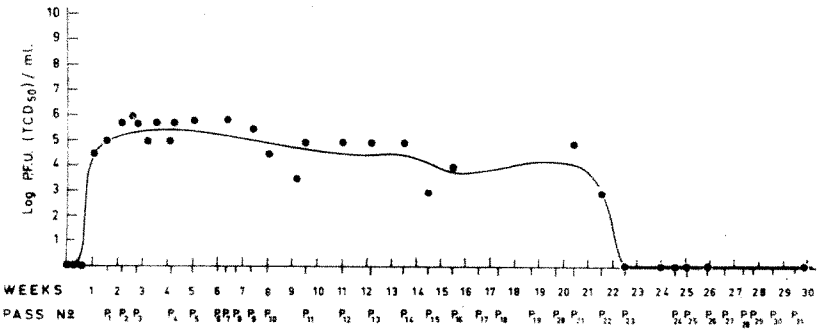

Fig. 1. Titres in supernatant fluids of Chang liver cell cultures persistently infected with echovirus type 9

changed and cell passages were carried out every fourth and seventh day respectively, the cells multiplying at a rate similar to that of uninfected cells. The virus concentration in the supernatant fluid remained more or less constant up to the fourteenth week, when virus titres started to fall abruptly. No virus could be detected starting from the twenty-second week. Repeated attempts to isolate virus from the cells on monkey kidney and Chang liver cell monolayers, either by plating out up to 10^7 intact cells, or by the seeding of cells disrupted by ultra-sound or by freezing and thawing, were unsuccessful. The cell cultures thus obtained have been free from infectious virus now for twenty-five consecutive passages.

Several experiments were carried out in order to elucidate the mechanism of this persistent infection and the nature of the 'spontaneous cure' which terminated the virus carrier state. The number of infected cells was determined at the fourth, eleventh and fifteenth passage levels. This was done by plating out varying numbers of cells on monkey kidney indicator cells, after treatment of the versene-dispersed cell suspensions with echovirus type 9 antiserum. The percentage of cells yielding 1 P.F.U. was calculated and found to be 5·0 per cent, 2·8 per cent and 1·1 per cent respectively. These results would indicate that (*a*) only a small proportion of the cells yields infective virus, which varied at these passages between 1 in 20 and 1 in 95, and (*b*) with the passage of the persistently infected cultures, the number of cells yielding virus decreases. In addition, at the eleventh and fifteenth passage levels, the ratio of P.F.U. from whole and disrupted cells was determined and found to be close to unity, indicating that each yielding virus cell releases only 1 P.F.U. at a time. These results are in accord with those reported by Deinhardt *et al.*[5] for MCN_{NDV} carrier cultures, and suggest that the mechanism of the chronic cell infection may be mediated by interferon[6]. In preliminary experiments, small amounts of interferon were detected in the supernatant fluids of the carrier cultures at the third, eleventh and fifteenth passage levels but not in the spontaneously cured cells.

The most intriguing finding was the spontaneous disappearance of the virus from the $Chang_{Echo\text{-}9}$ carrier cultures. The spontaneously cured $Chang_{Echo\text{-}9}$ cells were tested for susceptibility to homologous as well as to heterologous viruses. The strain of echovirus type 9 which had initiated the virus carrier state was used for homologous challenge, and poliovirus type 1 and coxsackievirus type B_1 as heterologous viruses. All three viruses are cytopathogenic for parent Chang liver cells. Uninfected parent Chang liver cells, kept and passaged in an identical growth medium, served as controls. Preliminary experiments carried out in tube cultures have indicated that the cured $Chang_{Echo\text{-}9}$ cells are resistant to a challenge dose of $10^{7\cdot5}$ P.F.U. of echovirus type 9 which constituted a multiplicity of infection of 320. Table 1 shows the mean values of three challenge experiments. The spontaneously cured $Chang_{Echo\text{-}9}$ cells are completely resistant to challenge with homologous virus. On the other hand, these cells are highly susceptible to both poliovirus type 1 or coxsackie virus type B_1, the efficiency of plating of these viruses on spontaneously cured $Chang_{Echo\text{-}9}$ cells being almost equal to that on control Chang liver cells. All the challenge tests were carried out in the absence of serum. Once resistance had been established, serum was not necessary for its maintenance.

Table 1. HOMOLOGOUS AND HETEROLOGOUS CHALLENGE OF SPONTANEOUSLY CURED $CHANG_{Echo\text{-}9}$ CARRIER CELLS

Cells used for plating	No. of P.F.U. after challenge with* Echovirus type 9	Poliovirus type 1	Coxsackie virus type B_1
Spontaneously cured $Chang_{Echo\text{-}9}$	0·0	8×10^6	$5{\cdot}5 \times 10^6$
Control—Chang liver	9×10^6	$1{\cdot}2 \times 10^7$	2×10^7

* Numbers represent mean values of three experiments.

The nature of this cell resistance is as yet unknown. Adsorption experiments indicate that it is not due to lack of specific virus receptors, since 95 per cent of echovirus type 9 are adsorbed to the cells within 1 h at 37° C, which is similar to its rate of adsorption to parent Chang liver cells. Walker and Hinze[7] have shown in *C-M* carrier cultures that these are specifically resistant to homologous but not to heterologous challenge, and that 80–95 per cent of the cells contain viral antigen. It is possible that in our system resistance may also be due to the presence of viral antigen. However, the *C-M* cultures, unlike the spontaneously cured $Chang_{Echo\text{-}9}$ cells, have been shown regularly to release virus. In most virus carrier cultures studied (see refs. 8 and 9), resistance is due to the presence of virus in the cells; when the cultures are cured with antiserum, their susceptibility to homologous virus is restored. In a number of virus carrier systems[10–12], increased cell resistance to homologous challenge is observed in the absence of virus release.

Vogt and Dulbecco[12] interpreted this increased resistance on the basis of selection of resistant cell mutants preexistent in the cell population. Such a mechanism may also explain the cell resistance obtained in the $Chang_{Echo\text{-}9}$ system, in which the selective pressure resulted in repopulation of the cultures with resistant cells. One may speculate on the possibility that similar mechanisms operate in the development of cell resistance under natural conditions. As an example may serve the ill-understood 'intestinal resistance' to poliovirus—either wild or induced by attenuated strains—obtained by repeated infections of the intestinal tract. This intestinal resistance is also type-specific in analogy with the $Chang_{Echo\text{-}9}$ spontaneously cured cells.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, May 2

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 2.30 p.m. and 5 p.m.—Colloquium on "Current Topics in Tropospheric Propagation".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5 p.m.—Annual General Meeting.

UNIVERSITY OF LONDON (at the Wright-Fleming Institute of Microbiology, St. Mary's Hospital Medical School, London, W.2), at 5 p.m.—Dr. D. C. Phillips: "The Structure and Function of Lysozyme" (first of a series of four Almroth Wright Lectures).*

SOCIETY OF CHEMICAL INDUSTRY, LONDON SECTION (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Annual General Meeting, followed by Dr. R. J. Wicker: "Some Thoughts on Sweetening Agents, Old and New" (chairman's address).

INSTITUTION OF ELECTRICAL ENGINEERS, LONDON GRADUATE AND STUDENT SECTION (at Savoy Place, London, W.C.2), at 6.30 p.m.—Annual General Meeting, followed by Dr. W. T. Norris: "M.H.D. Generation of Electricity".

Tuesday, May 3

UNIVERSITY OF LONDON (at the Royal Free Hospital School of Medicine, 8 Hunter Street, Brunswick Square, London, W.C.1), at 5 p.m.—Prof. M. J. Blunt (University of New South Wales): "The Structure and Function of Macroglia".*

UNIVERSITY OF LONDON (at Westminster Medical School, Horseferry Road, London, S.W.1), at 5.15 p.m.—Dr. J. A. Waddell: "Flow in Collapsible Tubes or the 'Waterfall' Phenomenon".*

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, London, S.W.1), at 5.30 p.m.—Mr. F. Walley: "Some Special Applications of Prestressed Concrete to Civil Engineering Structures".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Prof. R. J. Harrison: "Marine Mammals and the Sea". (Afternoon lecture for Fourth Form and Sixth Form Boys and Girls from Schools in London and the Home Counties. To be repeated on May 4, 10 and 11.)

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, London, S.W.7), at 5.30 p.m.—Prof. J. W. Dungey: "The Magnetosphere" (Inaugural Lecture)*.

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, Royal School of Mines, London, S.W.7), at 5.30 p.m.—Prof. D. W. Fuerstenau: "Mineral-Water Interfaces. I. Principles and Problems of Interfacial Behaviour".*

UNIVERSITY OF LONDON (at the Institute of Archaeology, 31–34 Gordon Square, London, W.C.1), at 5.45 p.m.—Prof. J. D. Evans and Mr. A. C. Renfrew: "Excavation in the Neolithic Settlement at Saliagos, Antiparos, 1965".*

PLASTICS INSTITUTE, LONDON SECTION (at the Wellcome Building, Euston Road, London, N.W.1), at 6.30 p.m.—Annual General Meeting.

Wednesday, May 4

COLOUR GROUP (Great Britain) (at the National Gallery, Trafalgar Square, London, W.C.2), at 2.30 p.m.—Fifth Annual General Meeting. 3 p.m.—Mr. H. Rohemann: "Art and Technique in the Restoration of Pictures".

ROYAL STATISTICAL SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5 p.m.—Prof. J. F. C. Kingman. "An Approach to the Study of Markov Processes".

ROYAL SOCIETY OF MEDICINE, HISTORY OF MEDICINE SECTION (at 1 Wimpole Street, London, W.1), at 5.15 p.m.—Annual General Meeting, followed by Dr. Charles Newman: "Medical Education in Our Time".

INSTITUTION OF CHEMICAL ENGINEERS (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Dr.-Ing. Walter Ludewig: "Highlights in the History of BASF".

ROYAL MICROSCOPICAL SOCIETY (at the Institute of Ophthalmology, Judd Street, London, W.C.1), at 5.30 p.m.—Conversazione.

UNIVERSITY OF LONDON (in the Gustave Tuck Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. Alfred Tarski: "On Undecidable Theories" (further lectures on May 11 and 12)*.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN (at 17 Bloomsbury Square, London, W.C.1), at 6 p.m.—Prof. G. B. Marini Bettòlo: "The Evolution of Pharmacopoeias in Europe".

Thursday, May 5

ROYAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Dr. F. H. C. Crick, F.R.S.: "The Genetic Code" (Croonian Lecture).

UNIVERSITY OF LONDON (at Bedford College, Regent's Park, London, N.W.1), at 5.15 p.m.—Prof. L. S. Hearnshaw: "The Comparative Study of Mental Development".*

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, London, S.W.1), at 5.30 p.m.—Informal Discussion—"Report on the Washington Conference on Desalination" introduced by Prof. Silver.

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. P. J. Lambeth, Mr. J. S. T. Looms, Mr. A. Stalewski and Mr W. G. Todd: "Surface Coatings for H.V. Insulators in Polluted Areas"; Dr. F. H. Last, Mr. T. H. Pegg, Mr. N. Sellers, Mr. A. Stalewski and Mr E. B. Whittaker: "Live Washing of H.V. Insulators in Polluted Areas".

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, Royal School of Mines, London, S.W.7), at 5.30 p.m.—Prof. D. W. Fuerstenau. "Mineral-Water Interfaces. II. The Adsorption of Surfactants".*

CHEMICAL SOCIETY (at the Royal Institution, 21 Albemarle Street, London, W.1), at 6 p.m.—Prof. J. D. Roberts (California Institute of Technology): "Studies of Conformational Equilibration by Nuclear Resonance Spectroscopy" (Centenary Lecture).

INSTITUTE OF REFRIGERATION (at the National College for Heating, Ventilating, Refrigeration and Fan Engineering, Southwark Bridge Road, London, S.E.1), at 6 p.m.—Meeting on "Medical Applications of Refrigeration". Dr. D. K. Brooks: "Total Body Cooling in Man"; Dr. D. E. Pegg: "The Preservation of Living Cells and Tissues at Very Low Temperatures".

SOCIETY OF CHEMICAL INDUSTRY, MICROBIOLOGY GROUP (at 14 Belgrave Square, London, S.W.1), at 6 p.m.—Annual General Meeting. Prof. G. F. Gause (Institute of New Antibiotics, Moscow): "Some Aspects of Antibiotic Research".

Friday, May 6

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Dr. F. Kingsley Sanders: "The Beginnings of Cancer".

Monday, May 9

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Prof. L. Berry: "The Nile in the Sudan".

UNIVERSITY OF LONDON (at the Wright-Fleming Institute of Microbiology, St. Mary's Hospital Medical School, London, W.2), at 5 p.m.—Dr. R. C. Valentine: "The Construction of a Virus" (second of a series of four Almroth Wright Lectures).*

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "An Engineer's Ideas on Some of the Electromagnetic Fundamentals" opened by Mr. G. F. Shotter.

SOCIETY FOR VISITING SCIENTISTS (at the English Speaking Union, Dartmouth House, 37 Charles Street, London, W.1), at 7.30 p.m.—Discussion Meeting on "Teaching Methods in Biology and Medicine". Chairman: Dr. J. R. Ellis. Speakers: Prof. Marc Klein: "The Training of the Doctor in France"; Dr. J. Badenoch: "The Tutorial System at Oxford".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

SENIOR LECTURER and a LECTURER (with good academic qualifications and specialized in one of the following fields: circuit engineering or communications or computer engineering) IN THE DEPARTMENT OF ELECTRICAL ENGINEERING—The Principal, Lanchester College of Technology, Priory Street, Coventry (May 3).

DEMONSTRATOR/SENIOR DEMONSTRATOR IN THE DEPARTMENT OF GEOGRAPHY—The Registrar, The University, Newcastle upon Tyne, 2 (May 4).

HISTOLOGICAL TECHNICIAN IN THE DEPARTMENT OF PHYSIOLOGY, to run a histological laboratory in a new research group being set up to study the formation and regeneration of nerve connections—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (May 4).

JUNIOR FELLOW (preferably with experience of research in mycology) IN BOTANY—The Registrar, University Senate House, Tyndall Avenue, Bristol, 2 (May 4).

JUNIOR FELLOW IN THE DEPARTMENT OF PHYSICAL CHEMISTRY to partake in a programme of research on the synthesis and crystallization of polymers, and the influence of polymer morphology on the kinetics of polymer degradation, and the structure of polymer carbons—The Registrar, University Senate House, Bristol, 2 (May 6).

LECTURER (Grade II) IN THE DEPARTMENT OF PHYSICAL CHEMISTRY—The Registrar, University Senate House, Tyndall Avenue, Bristol, 2 (May 6).

ASSISTANT LECTURER (with a thorough training and research experience in X-ray crystallography and an interest in its applications of mineralogical problems) IN CRYSTALLOGRAPHY IN THE DEPARTMENT OF GEOLOGY IN THE FACULTY OF SCIENCE—The Registrar, The University, Manchester, 13, quoting Ref. 102/66 (May 7).

ASSISTANT LECTURER (with a wide interest in cytology so as to be able to lecture to students of both departments) IN CYTOLOGY IN THE DEPARTMENTS OF BOTANY AND ZOOLOGY IN THE FACULTY OF SCIENCE—The Registrar, The University, Manchester, 13, quoting Ref. 84/66 (May 7).

ASSISTANT LECTURER (with an honours degree and experience in research, industry or teaching) IN ELECTRONICS IN THE DEPARTMENT OF APPLIED PHYSICS—The Registrar, Welsh College of Advanced Technology, Cathays Park, Cardiff, quoting Ref. No. DN741 (May 7).

LECTURER IN THE DEPARTMENT OF SOCIOLOGY—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (May 7).

LECTURER or ASSISTANT LECTURER (preferably with a particular interest in recoil chemistry or radiation effects in solids) IN CHEMISTRY to specialize in radiochemistry—The Registrar, The University, Manchester, 13, quoting Ref. 103/66 (May 7).

LECTURER or ASSISTANT LECTURER (with qualifications and experience in either Greek philosophy or logical theory or, preferably, both) IN PHILOSOPHY—The Registrar, University College of Swansea, Singleton Park, Swansea (May 7).

LECTURERS or ASSISTANT LECTURERS (2) (with research experience in any of the branches of electrical engineering) IN ELECTRICAL ENGINEERING IN THE FACULTY OF SCIENCE—The Registrar, The University, Manchester, 13, quoting Ref. 99/66 (May 7).

LECTURER or ASSISTANT LECTURER IN STATISTICS IN THE DEPARTMENT OF MATHEMATICS—The Registrar, The University, Leeds, 2 (May 9).

RESEARCH ASSISTANT (suitably qualified graduate with interest/experience in the field of either physical chemistry or physical biochemistry) IN THE DEPARTMENT OF CHEMISTRY AND BIOLOGY—The Principal (Dept. N), Harris College, Corporation Street, Preston (May 9).

ASSISTANT KEEPER (with some training and an interest in invertebrate zoology) IN ZOOLOGY at the Manchester Museum—The Registrar, The University, Manchester, 13, quoting Ref 105/66 (May 14).

LECTURER (with special interests in high polymer chemistry) IN PHYSICAL CHEMISTRY—The Secretary, The University, Aberdeen (May 14).

RESEARCH ASSISTANT (graduate with a special interest in electron microscopy) IN BOTANY—The Professor of Botany, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (May 14).

RESEARCH ASSISTANTS (with a university degree, or equivalent, in chemistry or physics, and preferably experience in electronics) IN THE DEPARTMENT OF CHEMISTRY to participate in a research programme, financed by S.R.C., on the application of electron spin resonance technique to the study of chemical reactions—The Secretary, The University, Aberdeen (May 14).

RESEARCH DEMONSTRATORS (with research interests either in organic or physical chemistry) IN CHEMISTRY—The Registrar, University College of Swansea, Singleton Park, Swansea (May 14).

LECTURER or ASSISTANT (registered medical practitioner) IN THE DEPARTMENT OF FORENSIC MEDICINE—The Registrar, The University, Leeds, 2 (May 16).

LECTURER (with a distinguished academic record in mathematics, preferably with interests in a branch of applied mathematics and some experience in computing) IN MATHEMATICS at Wollongong University College, University of New South Wales—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, May 16).

THIRD FOUNDATION CHAIR IN BIOLOGY, La Trobe University, Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, May 16).

LECTURER (with experience of modern cartography, preferably in association with a large national mapping organization) IN CARTOGRAPHY at Victoria University of Wellington, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, May 18).

LECTURER (non-medical, preferably with experience in immunology) IN CHEMICAL MICROBIOLOGY IN THE DEPARTMENT OF BACTERIOLOGY—The Registrar, The University, Liverpool, quoting Ref. CV/16/N (May 20).

LECTURER (with special interests in physical organic chemistry) IN ORGANIC CHEMISTRY—The Secretary of the University Court, The University, Glasgow (May 20).

LECTURERS or ASSISTANT LECTURERS (3) IN THE DEPARTMENT OF SOCIOLOGY AND SOCIAL ANTHROPOLOGY (one appointment will be in social anthropology and two in sociology)—The Registrar, The University, Hull (May 20).

ASSISTANT LECTURER/LECTURER IN PSYCHOLOGY—The Registrar, The University, Keele, Staffs (May 21).

ASSISTANT LECTURER (preferably with an interest in some aspect of animal physiology) IN ZOOLOGY—The Registrar, The University, Manchester, 13, quoting Ref. 109/66 (May 21).

SENIOR LECTURER (medically qualified) IN PHYSIOLOGY—The Registrar, The University, Sheffield (May 21).

LECTURERS/ASSISTANT LECTURERS IN MATHEMATICS, CHEMISTRY, PHYSICS AND BIOLOGY at the Royal University of Malta—The Inter-University Council, 33 Bedford Place, London, W.C.1 (May 30).

PROFESSOR OF EDUCATION at the University of Waikato, Hamilton, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (May 30).

SENIOR LECTURER IN THE DEPARTMENT OF PATHOLOGY—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (May 30).

LECTURER IN PHYSICS (Theoretical) to join Dr. S. Doniach in a research group working on applications of quantum field theory to problems in solid state physics—Prof. M. Blackman, F.R.S., Physics Department, Imperial College of Science and Technology, London, S.W.7 (June 3).

CHAIR OF ELECTRONIC COMPUTATION IN THE DEPARTMENT OF APPLIED MATHEMATICS—The Registrar, The University, Sheffield (June 4).

ASSISTANT EDITOR (with experience of research and publication in medical or veterinary entomology, good critical faculty and ability to write lucid and concise English, but preferably a reading knowledge of other European languages) AT THE COMMONWEALTH INSTITUTE OF ENTOMOLOGY, LONDON, S.E.7, for duties which will include producing and editing the Institute's publications—The Secretary, Commonwealth Agricultural Bureau, Farnham Royal, Slough, Bucks (June 15).

BIOCHEMICAL GRADUATE (preferably postdoctoral) for the PROFESSORIAL SURGICAL UNIT LABORATORY to take part in research and supervise the biochemical work—The Secretary, St. Mary's Hospital Medical School, Paddington, London, W.2.

BIOCHEMIST (well qualified with suitable research experience) to lead a small group investigating the biochemistry of the mammary gland and related topics—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, quoting Ref. 66/N/15.

CHIEF TECHNICIAN IN THE DEPARTMENT OF ZOOLOGY to be in charge of the Technical Staff (25) of the laboratories—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh.

LECTURER or ASSISTANT LECTURER IN MATHEMATICS (Pure or Applied)—The Secretary, Royal Holloway College (University of London), Englefield Green, Surrey.

LECTURERS/ASSISTANT LECTURERS (4) (preferably with interests in one or more of the following subjects: vertebrate zoology, embryology, physiology, histology or marine ecology) IN THE ZOOLOGY SECTION OF THE DEPARTMENT OF BIOLOGICAL SCIENCES—The Registrar, Portsmouth College of Technology, Hampshire Terrace, Portsmouth.

PHYSIOLOGIST to join a small team of scientists studying the human environment—D. C. Page, Head of Personnel Services, The Electricity Council Research Centre, Capenhurst, Cheshire, quoting Ref. N/19.

RESEARCH ASSISTANT (suitably qualified chemist) for isotopic tracer studies of combustion mechanisms—Dr. C. F. Cullis, Department of Chemical Engineering and Chemical Technology, Imperial College of Science and Technology, London, S.W.7.

PROPER PLACE FOR TRANSPORT

WHAT is to happen about transport? Evidently there are huge and important changes in prospect. A decade or so from now, there will have been yet another transformation in the way in which people and their goods are moved from place to place. Old techniques are being faced with attenuation or even extinction, sometimes because better methods of travelling have come along but sometimes simply because the old methods have become intolerable.

The development of recent decades most obviously likely to be continued is the tendency for alternative methods of travel to co-exist, and so to offer potential travellers a choice. Within large cities, underground transport is usually an alternative to several ways of travelling on the surface. Roads, railways and airlines are in competition, and there are still people who cross the North Atlantic by sea. (Most freight goes that way, of course.) Choices between co-existing alternatives are usually made on rational grounds, although this does not imply that cheapness is all that matters.

In circumstances like these, even minor technical developments can trigger off marked changes in the pattern of transport. In Britain, electric traction promises to increase the distance over which railways can win passengers from airlines. Quite modest improvements of public transport in cities could do much to diminish congestion from motor cars. Oil tankers displacing 300,000 tons like that ordered from a Japanese yard by Gulf Oil could decisively affect the pattern of petroleum distribution from the major oilfields and—at the same time—encourage the pipeline operators, who offer the simplest and often the cheapest means of bulk transport. Then, there is the Boeing 747 aircraft, which is likely to do for people what the huge tankers will do for petroleum—trunk route transport will flourish, but getting off the beaten track will be increasingly troublesome. All these changes, promised or merely possible in the pattern of transport, have in common what is, in the broadest sense, an economic stimulus.

From this point of view, the benefits of new technical developments may be different from what their supporters intend. Thus, ironically, it could be that the first—and perhaps even the only—beneficial consequence of the Anglo-French project to build the *Concord* supersonic airliner will be to ensure that the operating costs of slower aircraft are steadily reduced. More soberly, there could well be a time, in the early 'seventies, when huge subsonic aircraft ply across the North Atlantic and similar routes, and smaller and faster aircraft travel less busy but longer routes. (It does not, of course, follow that the British and French Governments will recover their expenditure on the *Concord*.) Yet again, diversity seems to promise that the pattern of transport will be helped to find its most economic form. But what kind of diversity would be best?

Fast transport between cities separated by a few hundred miles is becoming urgently necessary in densely populated areas, particularly in Europe, North America and Japan. The United States Government is financing a number of exploratory investigations bearing on specific problems such as linking the major cities on the Atlantic seaboard. However, it remains to be seen whether the result will really reach beyond schemes for patching up the existing railway network to some of the more ambitious schemes which are sometimes heard of—monorails, pneumatic tubes with trains inside, and deep-bored tunnels intended to enable trains to oscillate from one city to another with no expenditure of energy except for overcoming friction and air resistance. One difficulty is that these transport studies, although well supported, are not being given the kind of attention lavished, for example, on getting to the Moon. In Britain, the somewhat comparable development of hovercraft, also likely to be important over distances of a few hundred miles (by sea or dry land), is not moving forward as vigorously as it might because of a tendency to expect that this device should show a profit from the beginning. Then intra-city transport systems of radically new design are being explored chiefly on the backs of envelopes.

There may eventually be even greater benefits to be won by planning cities, and indeed whole countries, in such a way that the advantages of novel kinds of transport networks can be exploited to the full. Within existing cities, for example, populations tend to be uniformly distributed on the ground, although with a density decreasing outwards from some central zone. The interactions between the distribution of population and an existing transport network tend to be limited to the proclivity for population to distribute itself, over the course of time, in such a way that all transport links are equally congested. It is, however, entirely conceivable that some quite different pattern of population would lend itself more easily to the use of fast transport links. If, within cities, populations were to be gathered into a number of more or less separate concentrations, it might be possible to win great advantages from potentially fast means of travel—monorails for example—which are not likely to be economic as simple replacements for existing underground railways. In other words, there is a strong case for asking that the fabric of a city and the means of transport used within it be designed as a delicately integrated whole. Similarly, cities should be designed or encouraged to develop in such a way as to cater more efficiently for the need to move people and goods easily from one to the next. This, after all, is how the great oil companies organize their affairs (although even they find it difficult to regulate the disposition of the eventual users of petroleum products).

How are ambitious plans of this kind to be formulated? Engineers by themselves are able to handle only part of the problem—the design and development of better ways of travelling. Architects and city planners are equally limited in what they can accomplish on their own, and are habitually but understandably accustomed to regard existing means of transport as permanent parts of the fabric of society.

A more active and vigorous interchange between city planners and transport engineers is a first necessity. Happily, there are signs of such a development in several countries—in the United States and Britain for example—and the use of computers for solving problems of planning is likely to foster the development. But there is also a need to attempt more deliberately to define the potential benefits of the co-ordinated planning of buildings

and transport. Obviously the money will have to come from governments, but responsibility for seeing that these developments begin rests principally with the technical community.

ASPHALT ECOLOGY

NATIONAL Nature Week, concerned with drawing attention to the place of non-human living things in Britain, has passed off without incident and without excessive sentimentality. The floods of argument which might have come from those who hold that all human interference with the environment is either dangerous or iniquitous did not materialize. Nobody seems to have been urging that fertilizers—not to mention insecticides —are poisonous. Animals of all kinds have had a fair showing, and the protective instincts of the British people have been lavished not merely on those animals commonly to be found in nursery rhymes, but also on stoats, starlings and snakes. The proceedings of the past week or so have been informed by a hard-headed appreciation that living things of all kinds give such great pleasure to all kinds of people that they are indispensable on that account alone But there is also growing up a keen awareness of how ecological considerations can have profound economic and social consequences even in localities where the density of human population is so great that most things are artificial. Evidently the propaganda of recent years has had a beneficial effect, which does great credit to bodies such as the Nature Conservancy, the Council for Nature and the host of smaller societies and associations, some local and some specialized, which have been drumming up support for constructive conservation.

It remains to be seen what will be the consequences of this activity. In Britain, growing concern for the problems of conservation has been accompanied by a resurgence of interest in the acquisition and the management of natural countryside. Buying up the remaining tracts of unspoiled coastline is an obvious but worthy goal. Extending the system of national parks is sensible, although the new arrangements for their administration which have recently been spelled out by the British Government are defective in many ways (see p. 574 of this issue of *Nature*). These, however, are the more passive components of a policy on conservation. There is also a growing need for machinery that will more actively ensure that the human environment is sensitively adapted to human needs. Ridding rivers of pollution is high on the list of priorities, and there is bound to be great interest in the proposals in the United States for cleaning major rivers which have been heavily polluted by industrial and other effluents. If, as some proclaim, it will be possible to turn the Hudson into a pleasant flowing stream again, there will be grounds for hoping that salmon may yet be fished from the Thames at London Bridge. But there are also the coal-tips and other spoil heaps to be carted away. Most people breathe heavily polluted air, and deserve better. And given the difficulty inescapable in crowded countries of finding somewhere to swim on warm days, might not schemes be seriously considered for making enough inland water space to satisfy the growing need? In other words, there is no sharp dividing line between conservation in the traditional sense and environmental engineering on the grand scale.

THE STRUCTURE OF POLYMORPHISM

Genetic Polymorphism

By Prof. E. B. Ford. (All Souls Studies, No. 5.) Pp. 101. (London: Faber and Faber, Ltd., 1965.) 21*s*. net.

AT the beginning of the century those sharp discontinuities of variation in wild populations, which we know as polymorphisms, were a corner-stone of the case against Darwinism. Now the evidence which their study has afforded is one of the chief pillars of the Neo-Darwinian structure which genetics has been putting together for the past forty years. For, as Prof. Ford points out, polymorphism provides one of the relatively few situations in which evolutionary change proceeds in such a way and at such a speed as to be detected and analysed by observation and experiment. And no one has contributed more than Prof. Ford and his school to the analysis and understanding of polymorphism.

Much of the material discussed in *Genetic Polymorphism* has been used earlier by Prof. Ford in his *Ecological Genetics*; but now it is analysed specifically for the information it can give about the structure and evolution of polymorphic systems. Evidence is drawn from a wide range, from heterostyly in plants, from mimicry, especially in the butterfly *Papilio*, from the moth *Panaxia*, from snails, from the chromosome studies of *Drosophila* species, and from man; and, indeed, in a number of these cases the monograph provides a valuable summary of literature spread over many years and many journals. What emerges is that polymorphisms may serve a variety of functions and may operate in a variety of ways, but that they have a common genetical structure arising from a common response to the impact of natural selection.

Genetically a polymorphic system comprises two elements, the switching gene, or super-gene, on the segregation of which depends the determination of the characteristic differences in the population; and the background genotype, on the balance of which depends the adjustment of the different phenotypes to the function they discharge. Not all the evidence is presented for this bipartite structure, especially in relation to the determination of incompatibility in plants; but the evidence given is ample for the conclusions reached. It would, however, have been of interest to have had included an account of Thoday's production of polymorphism by artificial selection under experimental conditions in *Drosophila*, for this brings out especially well the point that Prof. Ford makes about the variety of the switching systems that the same form of selection can build up.

The genetic structure of polymorphism is treated not just statically as something that has evolved, but dynamically as something that continues along its path of evolutionary progression, even at times outlasting the forces of selection to which it owes its origin. We are shown the switching system as progressing from gene to increasingly complex super-gene, and the background genotype as the manifestation of a co-adaptation that arises and persists as the impact of natural selection determines. Like all systems, too, polymorphism has its inertia. The system may come into being as a result of forces other than heterozygous advantage, indeed in many cases it obviously has done so, but once the system is in being heterozygous advantage may arise merely as a by-product of the growth of the switching super-gene. And once it has arisen it can hold the polymorphism in the population even after its initial cause has vanished.

Prof. Ford's monograph is a short one, but it is packed with interest, not least in the chapter on man. We are indebted to him for it. KENNETH MATHER

SILICON TECHNOLOGY FOR THE SEMICONDUCTOR INDUSTRY

Silicon Semiconductor Technology

By W. R. Runyan. (Texas Instruments Electronics Series.) Pp. ix+277. (New York: McGraw-Hill Book Company, Inc.; Maidenhead: McGraw-Hill Publishing Company, Ltd., 1965.) 132*s*.

GERMANIUM and silicon have dominated semiconductor technology for the past twenty years and the progress made with their preparation has maintained for them leading places in semiconductor physics. The spur for the technological developments was not, however, primarily one of expectations of discoveries of new physical effects but rather the prospects of the large-scale manufacture of junction transistors. Germanium received most attention at first; that rare element, previously little investigated, was soon to be made available more nearly completely purified and with greater crystalline perfection than any other substance. Its purification owed much to the development of zone refining, while the production of the large monocrystals with the controlled levels of impurity content required by the makers of devices was made possible only by the greatly improved control of the Czochralski method of pulling crystals from the melt and the adaptation of zone refining to zone levelling. No book has integrated these developments, other than by collecting together many of the original papers.

Similar studies with silicon started a little later; here again the spur was the prospect of industrial exploitation. Compared with germanium, silicon is a very abundant element and its supply does not depend on residues from other industries. Its conductivity, too, can be made *n*- or *p*-type, but its energy gap is one and a half times as great. For a given donor or acceptor concentration, it therefore retains its extrinsic properties to higher temperatures, and junction devices made in it can be used at temperatures up to 150° C or higher. The oxide which can easily be grown on it is not hygroscopic and might be expected to protect junctions from the detrimental effects of water vapour which were so noticeable with early germanium devices.

Progress with silicon benefited from that with germanium, but was not spectacular at first; the higher melting point and greater chemical reactivity presented problems. None proved insuperable, however, and the advantages predicted began to be realized. The silicon devices now available include high-voltage rectifiers, thyristors handling currents of 100 amp or more, transistors with gain-bandwidth products of 1,000 Mc/s, varactor diodes, solar cells and fully integrated electronic circuits; they testify to the success of the basic technology of this element. But, once again, no author had devoted a book to silicon technology until this recent addition to a newly launched series.

Silicon Semiconductor Technology is an educational book as well as one of reference. The order of presentation might be questioned, but frequent users will have little complaint to make on that score. After a short historical note, the second and third chapters describe briefly the chemical purification of silicon and methods for casting it into several shapes. The fourth chapter is more detailed in its account of crystal growing. It concentrates on pulling from the melt and growth from the vapour phase on to a substrate. The segregation of impurities during pulling or zone melting is well looked after, with data for several important elements. The next chapter surveys crystal systems before examining the diamond lattice in particular and telling how to determine the orientation of silicon crystals and the presence of twinning and of grain boundaries; but it fails to link up with the defects of the crystals grown by the methods of the previous chapter. The sixth chapter returns to doping procedures, listing the behaviour of the elements in common use as donors and acceptors, without adding much quantitative information to that already given. Diffusion of dopants is the subject of the next chapter; here the author keeps device technology to the fore with his choice of geometrical conditions and detailed attention to boron and phosphorus, the two elements of which the diffusion must be so accurately controlled in the planar technology. The next three chapters describe very competently the electronic, optical and other physical properties of monocrystalline silicon, relating them to composition. They would not be out of place in a book on semiconductor physics, but are just as needed here, for so many physical properties have to be taken account of in device technology. The final chapter switches to metallurgy, in the form of diagrams of binary phase systems, nearly forty in all, with silicon as one of the two elements throughout.

The author pleads that any description of surface behaviour would demand far more space than he could spare; but some account of the technology of thermally grown layers of silicon dioxide, and their role, was surely justified. Room for a chapter could have been found by omitting some absorption spectra and the phase diagrams of silicon and many metals with which it is only rarely associated, and by condensing some other figures.

The book is excellently produced, and almost all the basic technological data vital to the silicon semiconductor industry are presented clearly and in sufficient detail. Although the writing offends occasionally, particularly by its frequent and sometimes indiscriminate use of 'This' and 'this', the book is commended to everyone with a serious interest in the subject. J. R. TILLMAN

SOLAR RADIO ASTRONOMY

Solar Radio Astronomy

By Mukul R. Kundu. Pp. xi+660. (New York and London: Interscience Publishers, a Division of John Wiley and Sons, 1965.) 150*s*.

RADIO astronomy has taken a vigorous place in modern research since the Second World War. For ten years it was a compact subject, not too large to be covered by one reasonably comprehensive text. By 1956 Shklovsky recognized that this could not continue, and his book of that year dealt only with radio objects beyond the solar system. Now Dr. Kundu has shown that it requires a substantial book to cover the solar part of radio astronomy. It is very satisfying that, at the present time, the solar part is clearly defined and there is very little ambiguity concerning the material that should be included in a book entitled *Solar Radio Astronomy*.

The introductory chapters, 1–4, cover the relevant optical observations, radio propagation and emission, and observing techniques. The radio propagation theory is not very complete and reference to other texts may be necessary. Three radio emission processes are discussed under the titles "Bremsstrahlung", "Gyro-synchrotron Radiation", and "Cerenkov Radiation". These sections give the essentials of thermal, synchrotron and plasma emissions, all of which are required for explaining solar phenomena. There is a useful discussion on the Ginzburg and Zheleznyakov theory of coupling between plasma and electromagnetic waves. The developments of interferometry for solar radio purposes are described.

The central theme of the book is contained in Chapters 5–12, which deal systematically with the emission described as: quiet sun; slowly varying emission; cm bursts; dm bursts; meter bursts of types II, III, *U* and V; type IV radiation; noise storms and type I bursts. Each type of radiation is treated in a separate chapter and this makes it somewhat difficult to interrelate the burst phenomena until the threads are gathered together in Chapter 11. The great significance of the type IV synchrotron emission and its various manifestations is well portrayed.

Chapters 13–18 are more of a miscellany. Radio emission variations are so widely used as quantitative measures of some forms of solar activity that it is necessary to discuss the factors with which they correlate. This has led to a chapter on solar X-ray emission which points out the X-ray relations but rather neglects the rest of the ionizing ultra-violet spectrum. The radio phenomena of individual sunspot groups are shown to affect their relations with geomagnetic storms, polar cap events and cosmic ray bursts observed on Earth. These lively modern problems are well discussed. It has also been necessary to discuss the observations of those discrete cosmic sources which can be seen through the extended outer regions of the corona. Such observations make it possible to trace the characteristics of the solar wind most of the way towards the Earth. Finally, reference is made to the direct radar reflexion obtainable from the Sun.

The book is well set up and well illustrated. It keeps very close to the research problems of the past few years and it does not minimize the difficulties of interpreting the highly varied phenomena. It will be essential for all who are studying either radio astronomy or solar phenomena, and should have a wide use for general reference.

C. W. ALLEN

WHAT IS A ROBOT?

Human Robots in Myth and Science

By Prof. John Cohen. Pp. 156+16 plates. (London: George Allen and Unwin, Ltd., 1966.) 35*s*. net.

PROF. COHEN uses the word 'robot' in the broadest possible sense as any self-regulating artefact which operates without human aid. The first five chapters of *Human Robots in Myth and Science* are really concerned with mythology and literature which are of interest to the psychologist and the historian rather than to the applied physicist. The applied physicist is concerned with much more precise definitions of terms since he has the task of carrying the industrial revolution into its second stage. The first industrial revolution was the replacement of human muscle power by heat engines. The second is concerned with the replacement of human attention by automatic devices.

In my opinion the word 'robot' should only be applied to one particular group of automatic devices. Thus we can distinguish between the computer, automatic control devices, the telearchic machine, specialized machines and the true robot. Basically, the computer can only carry out operations with numbers, although these can be highly complex and very fast and include remembering and taking definite action according to the result of an earlier stage of the calculation. Except when a deliberate random element is built in, the computer is, however, mainly carrying out as accurately as possible and very fast the instructions given to it by men. Automatic control devices can take in, from a small number of instruments, numerical observations of physical factors and operate a number of controls on a piece of equipment in a way which has again been built into them by a man. The telearchic machine is simply a device for enabling a man, seated at a control panel in a convenient and comfortable position, to receive sense impressions from a dangerous region and to instruct a machine movement by movement in carrying out complex operations. Specialized machines save labour by enabling a man to do very much faster and more efficiently something that he could do crudely with his hands. This category also includes machines for providing a substitute for a missing part of a man.

The true robot is like a man to the extent that it can do a whole variety of different tasks and in that it receives a certain number of sense impressions so that it can adapt its operations to a limited range of external circumstances. However, it can only (like the computer or the automatic control device) act in precisely the way in which it has previously been instructed by a man. It can also only carry out movements according to its previously given instructions. This definition of a robot surely gives a clear answer to the question posed in the title of the final chapter "Is Man a Robot?". Man differs basically and essentially from a robot in the fact that he can use free will to work out where he wants to go and what he wants to attain and then make his own plan of operations. In Prof. Cohen's book the ascetic is quoted as an example of the most robot-like of humans. I should take exactly the opposite view. The ascetic is the man whose thoughts about his purpose in life have led him to do the actions which are most uncomfortable from the point of view of his physical body.

Neither robots nor computers will ever be able to make an original invention, a really creative work of art, to think of a new scientific hypothesis or to write a good book either on philosophy or on fiction. This is quite simply because not only do they not have free will but they also lack what the author refers to as "the seat of emotion". No creative work of any kind can be done by purely logical processes of juggling concepts or numbers about. It requires the working together of logical understanding and the emotional process of creativeness. It follows that if humans have a capability for having useful emotions and a possibility of free will which can never be built into any machine, then we have a perfect moral right to treat machines as slaves to serve our purposes. Prof. Cohen discusses the possibility of using animals as slaves, but there is little doubt that in the next 20 years machines can be developed to serve the needs of mankind far more efficiently than animals. There is already in the United States a machine with one hand which can carry out two hundred successive handling operations exactly as it has been instructed. These operations are stored on magnetic tape.

The big research problem for the applied physicist is to give these robots more advanced ways of being aware of changes in external circumstances and of responding to these changes appropriately.

M. W. THRING

FORMATION OF ANTIBODIES

Molecular and Cellular Basis of Antibody Formation

Edited by J. Šterzl, with the co-workers of the Immunological Department. (Proceedings of a Symposium held in Prague on June 1–5, 1964.) Pp. 683. (Prague: Publishing House of the Czechoslovak Academy of Sciences, 1965.) 82 Kčs.

MOLECULAR and Cellular Basis of Antibody Formation records the proceedings of an international symposium held in June 1964 and organized by the Immunology Department, Institute of Microbiology, Czechoslovak Academy of Sciences. The meeting was devoted mainly to chemical and biological problems related to antibody formation. The communications are arranged in five sections: (1) nature of immunogenicity (five papers); (2) characterization of antibodies (sixteen papers); (3) primary response in antibody formation (nineteen papers); (4) secondary response in antibody formation (five papers); (5) theories of antibody formation (two papers). The discussion which followed each paper is briefly recorded and each section concludes with a more extended account of exchanges among the eighty-two participants in the symposium.

The first in this series of meetings was held in Prague and Liblice in 1959; the proceedings were published in 1960 and re-issued 2 years later in a book entitled *Mechanisms of Antibody Formation*. Comparison of this first book with the present volume reveals how rapidly the understanding of many immunological processes has advanced during the intervening 5 years. This is especially obvious in regard to knowledge of the chemical and physical heterogeneity of immunoglobulin molecules, the structure

and complexity of their constituent peptide chains and the development and functions of the complex lineage of lymphoreticular cells which are involved in antibody synthesis. Other more refractory problems such as the fate of antigenic molecules, the mechanisms activating immunoglobulin synthesis and the chemical basis of antibody specificity continue to be investigated in many laboratories and are discussed by several contributors to this volume.

It is clearly not the purpose of these proceedings to review comprehensively the topics indicated by the sectional headings. The book provides a wealth of experimental detail and informed comment from those most actively engaged in advancing their subject. Although much of the work described has now appeared in the literature, the publication in a single volume of these contributions and the discussion which they provoked provides an absorbing record of present-day immunological research; the book will be of value and interest to all who are involved in the study of immunological processes.

S. COHEN

CANCER CHEMOTHERAPY

Cancer Chemotherapy

By Prof. L. F. Larionov. Translated from the Russian by A. Crozy. Translation edited by W. J. P. Neish. Pp. xx + 544. (London and New York: Pergamon Press, Ltd., 1965.) 140*s*. net.

PROF. L. F. LARIONOV is one of the leading experts on the chemotherapy of cancer in the U.S.S.R. He is also its strongest protagonist and *Cancer Chemotherapy* is intended not only as a text-book for those "actively participating in the development of chemotherapy" and "for teaching and the further training of medical personnel in the new practical branch of oncology" but also as a piece of propaganda directed against the sceptics. He campaigns trenchantly against those surgeons and radiotherapists who "still have not realized that, in many cases of cancer disease, chemotherapy can and must be incorporated into the arsenal of therapeutic measures".

How well has Prof. Larionov succeeded in his overt aim? It would be interesting to know whether, since the Russian edition was published in 1962, things have improved in the U.S.S.R. and whether the criticism would be accepted as valid in Britain in 1966. Clinicians will search in this book to see how chemotherapy can add to their ability to treat neoplastic diseases. There is much of interest here for them, but it is not always easy to find.

The most interesting section is that in which the author states the "General Principles of Cancer Chemotherapy". The first principle is quite obvious—that the sensitivity of tumours of different organs to a given drug varies within extremely wide limits. The second is more controversial—that the sensitivity of tumours of the same organ to different drugs also varies within very wide limits. From the clinical section of the book it is clear that, for those neoplastic diseases that in general respond to chemotherapy, any of a wide range of drugs may be chosen. Prof. Larionov also asserts quite definitely, when he presents the technique of treating Hodgkin's disease, that "the technique of use of the drug is decisive—even more important than the properties of the individual compounds". A 'two-and-a-half' principle might well have been included here that would point to the wide range of sensitivity of tumours of the same organ to the same drug.

The third principle states that the effect of a particular drug is inversely proportional to the mass of tumour tissues. The relevance of this to use of chemotherapy in the treatment of small metastases while leaving the primary tumour for surgical resection is developed in a later section. The validity of the 'fact' on which this principle is based is a little doubtful. The lower therapeutic result from the treatment of large tumour masses is more likely to result from the failure of drug penetration than from any mass action effect.

The fourth principle states that, as a rule, metastases are more sensitive to drugs than primary tumours, and the fifth repeats the first principle but applied to metastases.

The author then draws two conclusions: (1) that chemotherapy with presently available drugs holds out no hope for patients with massive primary tumours and large metastases; (2) that the most promising approach seems to be to use drugs in the treatment of small metastases and at an early stage in the disease.

But all these principles derive from the inadequacy of the antineoplastic drugs that are in use, and the subsequent section in the book that deals with the reasons for the low selectivity and minimal therapeutic efficiency of these drugs should have been stated first; so, too, should the basic justification for chemotherapy—that surgery and irradiation are powerless in the face of disseminated disease. In the management of cancers, clinicians have had to rely on inadequate drugs and only by great experience and maximum supportive therapy have significant results been obtained. One of the best examples, which has developed since the book was written, is the Acute Leukaemia Task Force sponsored by the National Institutes of Health in the United States.

The section of the book in which the limited capacities of the drugs are clearly in the author's mind is also one of the best. His carefully thought-out protocols for clinical trials of new drugs are excellent and written with an evident scientific scepticism.

It is difficult to be similarly enthusiastic about the other two sections of the book, however. Part 1, which deals with experimental screening of new compounds, and Part 2, entitled "Pharmacology", fall heavily between two stools. They are neither comprehensive nor are they critically selective. It is of no service to the clinician or the experimentalist to include a rambling account of so many transplantable tumours, when, in one sentence, the author puts the whole problem of screening in perspective with his comment "that there are still no good models of the most widespread and important human tumours".

For Part 2, "Pharmacology" is not the best-chosen name, for here we have a miscellany of the chemistry, biochemistry and clinical applications of too many drugs, as well as some of their pharmacology. Since study in depth of a few drugs is so clearly the way to obtain beneficial results at present, far too many substances which failed in clinical trials are included in this list.

Although the Russian text is probably 5 years old now, much of the book has aged very little. This does not perhaps suggest a very strong basis for the engaging optimism of Prof. Larionov's foreword. Progress will surely come in this field as fundamental research in molecular biology probes deeper into the nature of malignancy, but it will not be on the basis of relatively non-selective cytotoxic drugs.

As a final comment, the author has not been nearly so well served by his translator and editor as he deserves. 'Near English' and abundant errors remain in the text.

W. DAVIS

REGIONAL FARMING HISTORY

The Agricultural Revolution in South Lincolnshire

By David Grigg. (Cambridge Studies in Economic History.) Pp. xvi + 219. (London: Cambridge University Press, 1966.) 50*s*. net. = 10 dollars.

LOCAL history is in a flourishing state at the present time. The work carried out on the subject varies widely, both in the degree of scholarship it displays and in the skill with which the historian presents his conclusions.

The Agricultural Revolution in South Lincolnshire demonstrates painstaking research, mastery of English (though 'number' is a singular noun: Dr. Grigg uses it as plural) and an inclusive grasp of the different factors that affect the agricultural economy of a region.

South Lincolnshire is divided sharply by categories of soil, and slight but marked changes in elevation though little of it is above the 500-ft. level. From the coast to the Heath there are the marsh and the fen, divided into two parts, the silts and the peats, covering nearly half the area; then a low plain; then the Heath, beyond which the land declines again to the basins of the rivers Witham and Brant. The soils and the lack of efficient drainage and flood control made the task of the farmer one of great difficulty in the late eighteenth century, in spite of the long work of centuries on the rivers and flood areas. These natural impediments were not eased by the system of land holding, many acres of open fields being retained until the 1790's. Flood waters, too, restricted agricultural activities, some areas being known as 'half-year lands' because they could not be safely used for crops sown in autumn. Dr. Grigg has come to the conclusion that during the French Wars South Lincolnshire farming was "essentially extensive and technologically backward". Perhaps so ! Nevertheless, numerous and varied crops were grown on the drier fen and marsh, and the four-course rotation had been adopted, to some extent, on the Wolds and Heath by about 1790.

After victory in war at Waterloo, and even a year or so before, there was a drop in prices which hit farmers pretty hard. Many took the facile line of reducing production cost by neglecting drainage, reducing cultivations, economizing by letting land fall down, and so on. The South Lincolnshire farmers took the opposite line. They intensified their farming, introduced more fodder crops, roots and clover, where the soil was suitable, and generally adopted mixed farming, the most advanced system of the time. Between 1815 and 1850 this area, with suitable variations in the different geographical regions, became an example of how to meet financial handicaps by adopting a more intensive system giving a higher yield of crops and producing better breeds of livestock. Incidentally, the new methods made a greater demand for labour so that the whole system was more expensive although it was very much more productive. Dr. Grigg has collected evidence that seems to show that the average yield of wheat in South Lincolnshire was between 28 and 32 bushels an acre round 1850. This is very high and equal to the national average between the two World Wars. The sheep and cattle, too, were by then of outstanding quality. No significant change in the size of farms seems to have taken place during this period of development.

It remains to be seen whether other farmers in other districts recovered their financial stability by reason of adopting this risky and drastic procedure, or whether the recovery that took place by 1850, and lasted to the 1870's, was caused by general circumstances outside the farmer's control. I tend to the latter opinion, but the point is not yet clear. Meanwhile, Dr. Grigg's work deserves the closest attention, not only because it presents a novel but well-substantiated point of view, but also because it is an excellent example of how such studies should be carried out.

G. E. FUSSELL

PHYSIOLOGY OF VISION

Vision and Visual Perception

Edited by Prof. Clarence H. Graham. Pp. vii+637. (New York and London: John Wiley and Sons, Inc., 1965.) 180*s*.

THE number of experimental psychologists to have made notable contributions to the physiology of vision is small in Britain, yet there seem to be very many in the United States. Six of them have clubbed together and, encouraged by Clarence Graham, have produced the best book on visuology since Helmholtz. The comparison may seem unfair because Helmholtz did it all on his own and *Vision and Visual Perception* is a smaller volume, contributed to by six workers. However, the six had more to chew, digested it well, and the balance seems just about right: no man could be expected to deal authoritatively with all the ramifications of this bewildering topic and too many writers might have wrecked the script.

The contents are orthodox. By way of prolegomenon, we are treated to a description of the nature of light, photometry, basic optics, and—most welcome of all—to an account of how to set up the sort of apparatus used by the authors and many of those whose work they discuss. The outline of the structure of the visual system is helpful, although a comparison of Figs. 2·5 and 2·6 is irritating, and the description of the crystalline lens and its function outdated. To say categorically that there is no evidence of binocular fusion within layers of the lateral geniculate body is an admission of ignorance of the work of Bishop and his collaborators. The electrophysiology of vision is dealt with competently and fairly, but—as is inevitable in the tornado of data production that has built up—is beginning to assume the patina of history. The account of cortical activity is a masterpiece of assimilation and more useful than the more pretentious offerings of many an earlier author. But it is sad to have to report that the poor quality of the chapter on photochemistry is not due solely to the contrast it unfortunately offers to the rest of the book. The writer of this chapter has no 'feel' for the subject. There is nothing presumptive about difference spectra being unaffected by light-insensitive impurities, and the opinion that they consist of two portions is like saying that my overdraft consists of two parts: the money I owe to my bank and the money it is owed by me. The endless data on thresholds are well presented, and it is interesting to learn that frequency-of-seeing curves were used nearly 40 years ago. Brightness discrimination and contrast are related to electrophysiological data, and the modulation aspect of flicker is brought out with great clarity. However, the comparison of electro-retinographic fusion curves as obtained for cats, guinea-pigs, and pigeons (Fig. 10·15) would have gained in significance with an attempt to relate the stimulus to the retina, not to say the receptor types involved.

Visual acuity is discussed by a master although the omission of any reference to the transfer function of the eye is the most surprising gap to be found in the book: when was this chapter written? Colour vision is covered in five excellent chapters leaning perhaps a little heavily on concepts not readily subscribed to by physicists and physiologists, yet competent, searching, and fair. Vociferous authors, adulated by less critical writers, are dismissed irreverently though with justice. The discussion of the convergence of confusion loci leaves something to be desired, especially as it is going to be of decisive import in our acceptance or rejection of recent data on cone pigments. While the detailed treatment of the line-element is welcome, the account of Hecht's theory and the repetition of Laurens and Hamilton's data are surely prompted by feelings of piety. Contrast and related subjects, and after-images, have never been discussed in such detail and with such a sure touch. Again, the chapters on binocular vision, and perception of form and movement, while brief, are free from the noise of grinding axes.

Text-books are becoming more and more expensive and all but pricing themselves out of the student's wallet. However, this book is a must. It puts in the shade much of what went before and, if statistics is anything to go by, what the near future is going to bring.

R. A. WEALE

A Fundamental Survey of the Moon

By Dr. Ralph B. Baldwin. (McGraw-Hill Series in Undergraduate Astronomy.) Pp. viii+149+8 plates. (New York: McGraw-Hill Book Company, Inc.; Maidenhead: McGraw-Hill Publishing Company, Ltd., 1965.) 4.95 dollars; 40*s*.

BALDWIN has undoubtedly succeeded in presenting, in this work, a concise and readable account of a good deal of our knowledge of the Moon; as an introductory work for those not particularly specializing in lunar physics, it suffers little from the lack of mathematical analysis in certain places. However, the complete lack of mention in the text of the now well-established principles of lunar tectonics is regrettable. It is true that if the references given in the preface are consulted most of the existing points of view will be encountered. Readers who do not do this, however, will be left ignorant of much important recent work.

In particular, some of the conclusions drawn about the nature of the maria and marial features will, almost certainly, have to be modified in the future as a result of the work of Dobar and others on the physical features of igneous structures caused by the inherent lunar surface conditions, which receives only passing reference in the text. The concluding statement that "The 136-year-old argument (concerning the origin of the craters) is over", based only on the evidence of the *Ranger* photographs, is far too emphatic.

The errors in this book are usually those of omission as indicated here, and many of these may be intentional to keep the length of the work to a minimum; but attention should be directed to the paragraph on faults in Chapter 6 in which it is specifically, and incorrectly, stated that there is no evidence for lunar strike-slip faulting. Printing errors are virtually non-existent, but it is unfortunate that the reference chart and contour map given are in astronautical and astronomical convention respectively, making comparison unnecessarily tedious.

L. WILSON

Basic Bacteriology

Its Biological and Chemical Background. By Dr. Carl Lamanna and Prof. M. Frank Mallette. Third edition. Pp. xiv+1001. (Baltimore, Md.: The Williams and Wilkins Company, 1965. Distributed in the U.K. by E. and S. Livingstone, Ltd., Edinburgh.) 140*s*.

DR. CARL LAMANNA and Prof. M. F. Mallette, in the third edition of their *Basic Bacteriology: Its Biological and Chemical Background*, have aimed at bridging the gap between the elementary text-book and the advanced monograph. Chapters are included on the taxonomy, microscopy and staining, structure, growth, nutrition and metabolism of bacteria with a final, somewhat fragmentary account of chemical sterilization. The book retains its rather excessive coverage of physical and chemical principles which are not invariably related to bacteriological problems. Since the publication of the second edition, the developments in bacteriology have necessitated considerable revision and amplification, and genetics, protein synthesis, enzymology, photosynthesis and permeability have received greatest reappraisal. Unfortunately, but perhaps understandably in such a large work, the revision has been uneven. Thus, the discussion of numerical taxonomy, while adequate, is not exemplified and classifications derived from such analysis have not been compared with those based on the *a priori* hierarchy of characters. Such omissions are made the more conspicuous by the amount of space devoted to speculations on bacterial origins and phylogeny. Chapter 6 examines the structure of bacteria: here the presentation tends to be disjointed, sometimes confused, for example, the discussion of the cytoplasmic membrane and membranous organelles; or restricted, for example, the fine structure and division of nucleoids are not considered. More than one-third of the book is concerned with bacterial metabolism and variation, subjects which are treated with thoroughness and care, although inorganic nitrogen and lipid metabolism deserve a fuller exposition. The authors have omitted text references deliberately but provide extensive bibliographies and a good index. There are very few errors of fact and immense care has been taken with proof reading. This book will remain an important source of information on bacteria.

A. T. BULL

Lexicon Allergologicum

Allergologie Worterbuch. Herausgegeben von Knud Wilken-Jensen. (Allergology Dictionary.) Pp. xii+119. (London and New York: Pergamon Press; Leipzig: Johann Ambrosius Barth Verlag, 1965.) n.p.

WITH increasing interest in the clinical aspects of immunology, the amount of allergological literature has been growing fast. The European Academy of Allergology has played a leading part in facilitating communication in this field and now presents a six-language dictionary of terms most frequently used in the practice of allergy.

This dictionary is in three parts. The first part consists of an alphabetical list of 142 such terms, with language equivalents in German, English, French, Italian, Russian and Spanish. In the second part, 64 of these terms are explained in the form of brief sentences; these are given in six languages and will minimize errors in communication between practising allergists. The third part consists of language equivalents of 100 common allergens, in alphabetical order, with Latin terms where appropriate. The whole volume is of a convenient size for work in clinic and library.

Recent advances in immunology may soon permit more precise descriptions of allergological phenomena. That the European Academy of Allergology has been able to publish this lexicon is surely a pointer towards the eventual standardization of nomenclature in this field.

D. C. DUMONDE

Ultrastructural Plant Cytology

With an Introduction to Molecular Biology. By Prof. A. Frey-Wyssling and Prof. K. Mühlethaler. Pp. x+377. (Amsterdam, London and New York: Elsevier Publishing Company, 1965.) 130*s*.

ULTRASTRUCTURAL Plant Cytology sets out the personal views and the results of the extensive work of the authors on the fine structure of plant cells. The approach is direct, almost dogmatic, but this makes the text very readable and simplifies many complex and difficult concepts.

The first section of the book deals with the elementary organic and physical chemistry of large molecules and leads up to the modern theoretical discussions of the molecular basis of heredity and protein structure and synthesis. Rather surprisingly, no mention is made of the possible mechanisms of the control of cell differentiation and very little attention is paid to this very important branch of cytological research where work on plant material has made very significant contributions.

The second section describes the ultrastructure of the plant cell and attempts to relate these investigations to the account of the chemistry and molecular biology given in the first section of the book. The authors and their colleagues have contributed much to the subject matter of this section and a large amount of the factual information is taken from their many publications in the field. As a consequence, it is superbly illustrated with electron micrographs and with pictures from the new freeze-etch technique developed at the Zurich laboratories.

It is a good though expensive text-book for a course in cell biology.

D. H. NORTHCOTE

CHARTER CENTENARY OF THE ROYAL MICROSCOPICAL SOCIETY

THE Royal Microscopical Society will celebrate the centenary of the granting of its Royal Charter this year by holding international meetings in London (July 18–22), Chicago (August 22–26), and elsewhere.

It is now nearly 127 years since seventeen gentlemen sat down in a drawing-room in Wellclose Square, near the Royal Mint, London, "to take into consideration the propriety of forming a society for the promotion of microscopical investigation, and for the introduction and improvement of the microscope as a scientific instrument"[1]. The almost immediate result was the foundation of the Microscopical Society of London, with the famous anatomist, Richard Owen, as first President. The foundation of the Society set an example which was followed in many countries.

At its second meeting, in January 1840, an event occurred that has probably affected every biological laboratory in the world, namely the fixing of 3 × 1 in. as the standard size of the microscopical slide. A special instrument was provided on this occasion, which cut slides of the standard size for the members present. One of the most useful functions of the Society has been the standardization of microscopical equipment. Almost all microscope manufacturers in the world have accepted the standard R.M.S. thread for objectives and the standard R.M.S. diameters for eyepieces, so that the parts of the microscope are readily interchangeable from one instrument to another.

It had been anticipated that the Society would concentrate at the start chiefly on the improvement of the instrument itself, since achromatism and the effective correction of spherical aberration had only recently been introduced into microscopy, and further rapid advances might have been expected. Instead, the members turned mainly to the use of the improved instrument in biology. The celebrated John Quekett, one of the early members of the Society and its secretary for 19 years, was soon making full use of it in histology. Some of the best-known British biologists of the time joined the Society, among them Edward Newman, Bowerbank, Thomas Bell, George Busk, and T. H. Huxley; but those who were interested in the optics of the instrument and in the physical aspects of microscopy in general also became members. Among the most eminent of these were J. J. Lister and Faraday. Others again, like William Carpenter, were authorities on the construction and optical principles of the microscope, and also made full use of it in biological studies. The Society was an active and happy mixture of professionals and amateurs.

It was during the presidency of James Glaisher, famous as a meteorologist rather than as a microscopist, that the Royal Charter was granted, largely as a result of Glaisher's representations in the right quarters[2]. The grant was announced by him at a meeting of the Society on October 10, 1866, and in the following month it was announced that Queen Victoria had been graciously pleased to command that the Society should be styled the "Royal Microscopical Society"[3].

Some of the most important contributions to microscopy made in the succeeding decades by Fellows of the Society were those of J. W. Stephenson, who not only introduced a very successful erecting binocular microscope[4,5], the fore-runner of the dissecting microscopes of to-day, but also suggested the system of homogeneous immersion[6] for objectives that was adopted by Abbe[7] and brought to practical perfection by Carl Zeiss.

During the long stable period from the introduction of apochromatic objectives to the marvellous outburst of invention in the thirties and forties of the present century, the Society functioned largely by supporting and guiding the practical use of the microscope in various sciences, particularly biology. Certain of its Fellows contributed important general works on the instrument that retain their usefulness to-day, among them Dallinger's edition of Carpenter's *The Microscope and its Revelations*[8] and Spitta's *Microscopy*[9]. The example of E. M. Nelson (a President of the Society) contributed to the attainment in practice of the highest resolving power of which the instrument was at that time capable. The period was one of consolidation, with progress in limited fields, such as ultramicroscopy and the increase of resolving power by the use of ultra-violet light for illumination.

With the ever-increasing use of the microscope in the universities, the proportion of professional microscopists in the Society grew steadily, until in 1941 the President announced that "the amateur has practically disappeared"[10]. This, luckily, is not quite exact even to-day, for the fellowship of the Society is not exclusively professional, though amateurs are in a small minority.

The sudden advances that followed the quiet period changed the whole outlook of the Society, and interest was focused for a time on the instrument rather than on its applications. Only a quarter of a century ago the President had said that the electron microscope "may at first glance appear beyond the interest of microscopists"[10], and indeed the potentialities of the new instrument could not at that time be realized. Then came phase contrast and interference microscopy and the practical application of electron microscopy, and later the field-ion microscope. From these advances the Society received an enormous stimulus, and the fellowship increased rapidly. A new section of the Society was formed for the study and development of electron microscopy. Section membership, not confined to Fellows, became an established feature of the Society, spreading its usefulness much more widely. The applications of microscopy were not overlooked, and the institution of a Histochemical and Cytochemical Section brought another large group of active workers into the Society as Fellows or section members. The Society had long had a considerable fellowship in the United States, and in 1963, for the first time, a meeting of the Society was held outside Great Britain. This meeting, at the National Institutes of Health, Bethesda, under the presidency of Dr. V. E. Cosslett, was a great success, and resulted in a large increase in the American fellowship.

In recent years the Society has instituted courses of advanced instruction in optical and electron microscopy. These have been attended by enthusiastic groups of students, eager to obtain knowledge and skills that are not readily acquired at most universities.

The Society has also extended its general usefulness by starting a series of 'Survey Lectures' at its monthly general meetings. In these lectures a subject of wide interest is discussed by a recognized authority in the field, who gives an essentially personal account of recent developments. The Survey Lectures have attracted large audiences and will probably be a regular feature of the Society's activities.

The Society's chief ambition for the future is to found a permanent 'microscope centre', where instruction and research could be carried out in the same building. The intention would be to have optical and electronic instruments of the most advanced design in the centre, under the control of highly qualified research workers and technicians. The former, who would be free to plan their own researches, would be responsible for the instruction, for it is thought that teaching is best done by those actively engaged in research. There would be regular courses of general instruction, as well as facilities for obtaining information and practical advice on particular branches of microscopy.

Fellows of the Society have the necessary knowledge and experience to set up and run a centre of this kind, and it is earnestly hoped that means of financing it may be found. There is urgent need for such a centre, which would serve the interests of both science and industry. It may be mentioned that the total value of the electron microscopes already installed in Britain, with their accessory apparatus, probably exceeds £5 million, and it is very doubtful whether there are enough highly trained research workers and technicians to make full use of them.

The principal meeting to celebrate the granting of the Royal Charter will be opened by the President of the Society, His Royal Highness the Duke of Edinburgh, at 10 a.m. on July 18, in the lecture hall of the Royal Geographical Society, Kensington Gore, London. An elaborate programme has been arranged for this international meeting, the subject of which is "The Role of the Microscope in Scientific Investigation". There will be seven Survey Lectures addressed to the whole membership, and numerous group meetings to deal with the problems of the eighteen subjects into which microscopy has been divided for the purposes of more specialized discussion.

There will be important exhibitions, and in particular a very large display by British and foreign manufacturers of optical and electron microscopes and accessories. This, and the group meetings, will be held in the Imperial College of Science and Technology. A special feature of the manufacturers' exhibition will be a large display of functioning electron microscopes. There will also be receptions and visits to places of scientific interest in London, Cambridge and elsewhere.

The programme of the meeting and particulars of membership can be obtained on application to the General Secretary of the Society at Tavistock House South, Tavistock Square, London, W.C.1. J. R. BAKER

A BIOCHEMICAL INTERPRETATION OF SOME TAXONOMIC DIFFERENCES BETWEEN YEASTS*

By J. A. BARNETT

Low Temperature Research Station, Cambridge

SINCE the pioneer work of Wickerham[1,2] and Kudriavzev[3,4], taxonomists have been testing thousands of strains of yeasts on each of more than thirty compounds to determine which of these compounds can be a sole source of carbon for aerobic growth for each yeast (see, for example, ref. 5). This article proposes a method for examining associations between the results of such tests. The method is used to deduce the routes by which yeasts convert the test compounds into intermediates of the main metabolic pathways.

The method proposed for scrutinizing these results is analogous to that by which information on biosynthetic pathways has been obtained from auxotrophic mutants. The principle of the latter technique is that, if the requirements of two mutant strains are satisfied by the same substrate x, and of only one of the strains by substrate y, then y is the precursor of x (ref. 6). Even if such work was often incomplete in terms of its detailed enzymology, nevertheless it opened up new fields of intermediary metabolism[7].

Accordingly, this article considers biochemical schemes which follow logically from the results of taxonomic tests and which may explain these results. It discusses, particularly: (i) enzymes the presence of which in some yeasts and absence in others lead to correlations between the results of many of the tests; and (ii) how analysis of the results of large numbers of tests could be used to make evident the biochemical features that are likely to underlie these correlations. Such considerations may not only give a better understanding of the tests themselves, but may also help taxonomists to decide when they can legitimately treat nutritional characters as characters of 'equal weight'[8]. Such an analysis also provides a basis for generalizations about the initial catabolic steps for large numbers of yeasts with many substrates. Both these generalizations and also exceptions to them, which may be of particular interest, must eventually be subjected to experimental verification by the enzymatic examination of selected yeasts.

The results of the tests considered in this article are from two separate surveys which are part of a new major taxonomic study of yeasts being carried out under the direction of Dr. J. Lodder. The two surveys are: (i) Kreger-van Rij's recent investigation of the genera *Endomycopsis*, *Pichia* and *Debaryomyces*[5]; and (ii) unpublished observations of van Uden and his colleagues on *Candida* and *Torulopsis*[9]. The results discussed here are those of growth-tests with carbohydrates and their derivatives. Responses to such nutritional tests are generally presented (see ref. 5) in an all-or-none fashion (+ or −) and that is how they are treated here.

Reasons for failure to use substrates. A yeast fails to grow aerobically on a substrate either (i) because the substrate does not enter the cells[10,11], or (ii) because the yeast lacks one or more enzymes necessary to convert the substrate into an intermediate metabolite of a main pathway. Generally, only minor differences of carbohydrate catabolism seem to be concerned in the tests, not differences in major metabolic pathways (see refs. 12–14, ref. 15, p. 62, and refs. 16, 17).

It is not possible by growth-tests alone to distinguish between these two alternative reasons for failure. Caution is, therefore, necessary in drawing any conclusion as to the nature of a metabolic pathway from the results of growth-tests. Thus the existence of specific translocation mechanisms[18,19] governing the entry of substrates into the cells gives rise to a difficulty, which could interfere with analyses of the sort proposed. The absence of such mechanisms in certain yeasts can mask the presence of functional catabolic routes within the cells. Nevertheless, in this article it is assumed that failure to grow on a particular substrate reflects the absence of a catabolic enzyme, rather than the failure of a substrate to penetrate the cells.

Alternative catabolic routes for a single substrate. Every yeast that uses a given substrate does not necessarily do so by means of the same metabolic route. Sorbitol, for

* Substance of a talk given at the symposium on "Techniques for the Identification of Fungi" of the Society for General Microbiology and the British Mycological Society, held in London on January 6.

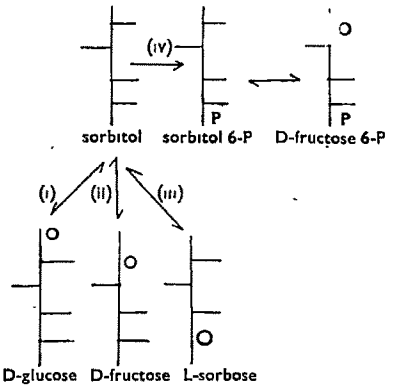

Fig. 1. Four alternative initial steps in the catabolism of sorbitol

example, could be oxidized to (i) D-glucose, (ii) D-fructose or (iii) L-sorbose; each oxidation requires a different dehydrogenase (usually coenzyme-linked)[20,21] (Fig. 1). The glucose and fructose thus produced would be metabolized through the Embden–Meyerhof pathway or the pentose cycle[22]. Sorbose, after phosphorylation[23,24], might be converted to glyceraldehyde and dihydroxyacetone phosphate[25]. There is, theoretically, a fourth possible route for sorbitol, namely, phosphorylation followed by dehydrogenation to, say, D-fructose 6-phosphate. Thus different yeasts perhaps use sorbitol in different ways. Consequently, when a taxonomist writes 'sorbitol +' for some yeasts and 'sorbitol −' for others, any one of four enzymatic mechanisms could be responsible for this distinction.

Interpretation of correlations of responses to different substrates. Taxonomists often find that most organisms which can utilize a certain substrate, *A*, can also use another, *B*, and conversely. Three alternative conditions may be responsible for such an association of responses to different substrates: (i) a catabolic enzyme, often that responsible for the initial attack on the test-substrate, may have a wide specificity; (ii) substrate *A* is converted into *B* as a step in *A*'s catabolic path; (iii) both *A* and *B* may be converted into *C*, a common metabolite of the route to the main pathway for both substrates.

Catabolic enzyme of wide substrate specificity. The polyol dehydrogenases[20] and the glycosidases[26] are well known for their wide specificities. An example is given by the β-glucosidases, a number of which have long been thought able to hydrolyse more than one substrate[27]. According to Herman and Halvorson[28], the β-glucosidase of a strain of *Saccharomyces lactis* hydrolyses arbutin, salicin and aesculin. The results of Kreger-van Rij's survey of the genera *Pichia*, *Debaryomyces* and *Endomycopsis* support the view that a single enzyme is responsible for hydrolysing various β-glucosides. Table 1 shows that, with only two exceptions, the yeasts which use arbutin also use cellobiose and salicin; and yeasts negative for one of these substrates are also negative for the others.

Interconvertibility of substrates. An example of substrate *A* being converted into substrate *B* is provided by D-ribose, which can be reduced to ribitol (adonitol) reversibly. Two possible routes (*X* and *Y*) for the catabolism of these two substrates are given in Fig. 2 (see ref. 29).

Table 1. RESULTS OF TESTING FIFTY-ONE SPECIES WITH THREE β-GLUCOSIDES

		Cellobiose		Salicin	
		+	−	+	−
Arbutin	+	33	0	32	2
	−	0	14	0	14

Entries in the table are numbers of species. +, Substrate utilized; −, substrate not utilized. From the observations of Kreger-van Rij (ref. 5) on *Endomycopsis*, *Pichia* and *Debaryomyces**.

* Of the fifty-one species, certain of them gave variable results from strain to strain: these results have been omitted.

Kreger-van Rij's survey[5] confirms, for the genera which she studied, that the utilization of ribitol is associated with that of D-ribose (Table 2). Were the two tests independent, the likelihood of obtaining the figures in Table 2 is less than one in a thousand (applying Yates's correction for continuity[30], $\chi^2_c = 16$, $n = 1$, therefore $P < 0{\cdot}001$). If (i) the initial step in D-ribose catabolism were always its reduction to ribitol (that is, route *X*, and not the formation of ribose phosphate); and (ii) the substrates are effectively unimpeded by cell membranes, then no yeast could be [D-ribose +, ribitol −]. If, on the other hand, ribitol were always first oxidized to D-ribose (route *Y*), then no yeast would be [ribitol +, D-ribose −]. The figures shown in Table 2 are consistent with the statement that D-ribose is converted initially to ribitol as in route *X*. They are inconsistent with route *Y*. Hence, analysis of the results of growth-tests with *Pichia*, *Debaryomyces* and *Endomycopsis* indicates that the first step in the catabolism of D-ribose is its conversion to ribitol.

Table 2. RESULTS OF AEROBIC GROWTH-TESTS WITH RIBITOL AND D-RIBOSE

		Ribitol	
		+	−
D-Ribose	+	18	0
	−	7	18

Explanation as for Table 1.

Table 3. RESULTS OF AEROBIC GROWTH-TESTS WITH L-ARABINOSE AND D-XYLOSE

		D-Xylose	
		+	−
L-Arabinose	+	17	0
	−	9	17

Explanation as for Table 1.

Common route to main pathway. The scheme in Fig. 3 (based on work with *Penicillium chrysogenum*[31] as well as with yeasts[29]) exemplifies the conversion of two substrates into a common metabolite. Thus, according to this scheme, both L-arabinose and D-xylose are converted, by way of xylitol, to D-threo-pentulose. In addition, the enzyme responsible for the initial reduction of L-arabinose may also catalyse the reduction of D-xylose[29,32]. There is evidence for the occurrence of such reactions in the yeasts *Candida utilis*[33], *Candida albicans*[32], *Rhodotorula glutinis*[34], *Saccharomyces rouxii*[35] and *Geotrichum candidum*[36].

Although the relationship between L-arabinose and D-xylose clearly differs from that described for D-ribose and ribitol, the figures from the taxonomic tests should be strictly comparable for both pairs of substrates. Provided that the scheme in Fig. 3 is true for yeasts, and that the substrates can penetrate the cells, a yeast able to use L-arabinose can also use D-xylose. As can be seen from Table 3, this proposition is true for species of *Endomycopsis*, *Pichia* and *Debaryomyces*[5]. It is also true for many other yeasts: Santa María[37] has found only one exception among 1,399 strains of yeasts of different genera isolated mainly from living insects and frass.

A method of handling the taxonomic data. For a satisfactory analysis, it is necessary to have more information about the results of the growth-tests than has usually been accessible hitherto. The results of the survey by Kreger-van Rij[5] are given only by species, and not by strain; certain species, therefore, have had to be omitted from the present analysis. The description[5] of *Pichia pinus*, for

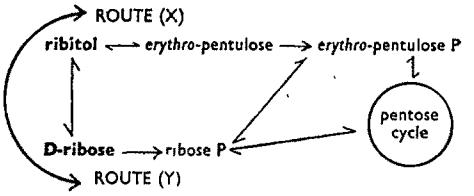

Fig. 2. Scheme for catabolism of D-ribose and ribitol

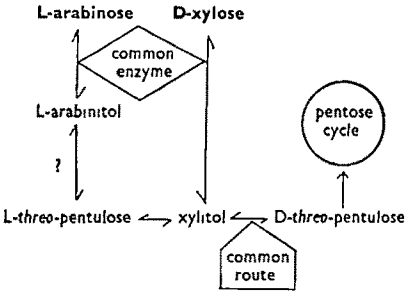

Fig. 3. Scheme for catabolic route of L-arabinose and D-xylose

example, indicates that the strains of this species differ in their reactions to D-xylose, L-arabinose and D-ribose; but it does not indicate whether a strain that uses, say, xylose can also use arabinose or ribose. Consequently, there is special interest in van Uden's observations on the ability of 293 strains (66 species) of *Candida* and 96 strains (32 species) of *Torulopsis* to grow aerobically on ten substrates[9]. These observations on individual strains have been arranged as tables of the kind already considered (Tables 1, 2 and 3).

The results of tests using L-sorbose and D-mannitol are given in Table 4. Again, these are not two independent tests ($\chi^2_c = 74$, $P < 0{\cdot}001$). The special interest of this table is that only eight strains out of 388 (that is, about 2 per cent) use L-sorbose but not D-mannitol. In other words, with only one exception in fifty (these perhaps impermeable to D-mannitol), if a strain of *Candida* or *Torulopsis* is able to use L-sorbose, it will also use D-mannitol. This relationship can be written L-sorbose ——◈ D-mannitol: in a more generalized form, so that A ——◈ B means that when substrate A is used, B is usually used, too, but not vice versa.

Table 4. RESULTS OF AEROBIC GROWTH-TESTS WITH L-SORBOSE AND D-MANNITOL

		D-Mannitol +	D-Mannitol −
L-Sorbose	+	208	8
	−	105	67

Entries in the table are numbers of strains of *Candida* and *Torulopsis* species. Data supplied by Dr. B. L. Brady (ref. 9). +, Substrate used; −, substrate not used.

The tables may be generalized in the form:

	$P+$	$P-$
$Q+$	a	b
$Q-$	c	d

The significance of the eight atypical yeasts (Table 4) found to be $Q+$, $P-$ (that is, b) is a function of (i) the total number of strains that are L-sorbose+ ($a+b=216$), (ii) the total number that are D-mannitol− ($b+d=75$) and (iii) the total number of strains ($a+b+c+d=388$). As the proportion in each case is small, namely, (i) $\frac{b}{a+b}=0{\cdot}037$, (ii) $\frac{b}{b+d}=0{\cdot}11$, it is reasonable to think of these eight strains as exceptions to a general rule.

It follows that it may be necessary to weight b according to the size of $(a+b)$. To take an extreme case, if in the above example $a+b=12$ and not 216, then $b=8$ would give little information about the relationship between P and Q. As a first attempt at weighting, a table of $\frac{100b}{a+b}$ was made for all the strains and substrates of van Uden's survey[9]. All pairs of substrates with $\frac{100b}{a+b} \leqslant 10$ (an arbitrarily chosen figure) are shown in the following system:

With not more than 10 per cent of exceptions, the system shows that (i) strains using any of the substrates, except xylose, used mannitol too; (ii) strains using any substrate listed in the left-hand column also used sorbitol; (iii) strains using D-arabinose or galactitol could use D-xylose. Certain examples of these interrelationships are discussed below.

L-Arabinose. L-Arabinose provides the first example: with six or seven exceptions, the strains that used L-arabinose also used sorbitol and mannitol (Table 5). Assuming that L-arabinose is in fact catabolized by way of xylitol (Fig. 3), then this relationship between L-arabinose, sorbitol and mannitol could be explained if (i) the enzyme responsible for xylitol ⇌D-threo-pentulose also catalyses sorbitol⇌D-fructose and (ii) a single enzyme is responsible for both D-mannitol⇌D-mannose and L-arabinose⇌L-arabinitol, as suggested by Horecker[29] with reference to his work on *Candida utilis*[33] and *Candida albicans*[32].

Table 5. RESULTS OF AEROBIC GROWTH-TESTS WITH L-ARABINOSE, SORBITOL AND D-MANNITOL

		Sorbitol +	Sorbitol −	D-Mannitol +	D-Mannitol −
L-Arabinose	+	166	6	165	7
	−	72	48	87	34

Strains of *Candida* species only, otherwise explanation as for Table 4.

Ten strains provide the exceptions to the L-arabinose/sorbitol/D-mannitol relationship (Table 5), of which six were described as '±' for L-arabinose[9]: that is, their ability to use L-arabinose is in doubt. None of the remaining four yeasts used D-mannitol, and only two of them used sorbitol. The behaviour of these four yeasts may be due to their impermeability to the polyols. There is evidence for such impermeability in a strain of *Candida utilis* which has been investigated in some detail. It contains an active dehydrogenase capable of converting sorbitol to D-fructose[34], but, in common with others of this species[9], this strain cannot utilize sorbitol for growth or for respiration, though it can use D-fructose[38]. Experiments with isotopically labelled sorbitol confirm that it does not enter the cells of this yeast[38].

L-Sorbose. The association discussed earlier between L-sorbose and D-mannitol (Table 4) may be explained by the hypothetical scheme shown in Fig. 4. Two transformations, namely, (i) L-sorbose⇌sorbitol and (ii) D-mannitol ⇌D-fructose, could be under the control of one enzyme, such as the NADP-linked dehydrogenase described for *Acetobacter suboxydans*[39–41]. There is evidence that extracts of *Candida utilis*[42] and of *Torulopsis candida*[38] can form L-sorbose reversibly from sorbitol. If yeasts that utilize L-sorbose always do so by the route shown in Fig. 4, then (ignoring any effects of permeability) such yeasts should use D-mannitol, too. The converse, however, would not be expected: first, the catabolism of sorbitol would be a necessary condition for L-sorbose utilization, though not for D-mannitol; secondly, D-mannitol may be oxidized by enzymes of other specificity, such as the one that converts it to D-mannose[29]. Were sorbose to be phosphorylated initially, there would be no obvious reason for its association with D-mannitol.

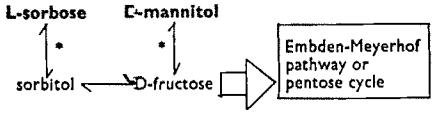

Fig. 4. Scheme for the catabolism of L-sorbose and D-mannitol. * The same enzyme is responsible for two transformations

Metabolic connexions between other substrates listed in this system will be discussed elsewhere. It is, however, worth noting that the position of D-mannitol in the scheme accords with Cochrane's observation[43] that "mannitol is the most generally utilizable of the hexitols, and is equivalent to glucose for many fungi".

Not enough has yet been done to determine the extent or nature of any metabolic differences between the groups of yeasts considered here. However, the mechanisms by which many test-substrates are utilized are clearly linked with each other. Shared enzymes and shared catabolic routes must both contribute to the correlations in the ability of yeasts to use different substrates: these associations are shown up by analysis of the taxonomic observations. The underlying mechanisms are linked, for instance, in the case of the polyols, pentoses and L-sorbose, which constitute about one-third of the test-substrates at present used for classifying yeasts. These substrates cannot be supposed to provide 'independent' tests. An appreciation of the underlying metabolic interrelationships, as well as of the statistical associations between the tests, is essential for a proper evaluation of the numerical taxonomists' practice of 'equal weighting', if that is to be considered as other than an *ad hoc* procedure.

In the past, a number of workers have proposed rules of associations between substrates based on the nutritional tests used for yeasts[44] or bacteria[45]. Many attempts have also been made to interpret the tests in metabolic terms, again both for bacteria[46] and for yeasts[12,47]. In this article a method has been described, which it is hoped to extend and to refine, and by which it is possible to scrutinize the behaviour of large numbers of strains. The increased use of carbohydrates and their derivatives in taxonomy has made this kind of investigation possible; and the yeasts, with their relative metabolic uniformity, are peculiarly suitable for such an analysis.

The method described here directs attention to (i) interrelationships between the results of nutritional tests, and (ii) exceptions to these interrelationships. Certain enzymatic or membrane characteristics have been proposed to explain these interrelationships and their exceptions. These proposals can be checked very readily by the enzymatic analysis of selected individual strains of those yeasts that have provided the general rules and also of those that have provided the exceptions. The method must stand or fall on its ability to predict the results of such analyses.

I thank Dr. B. L. Brady for compiling the observations on strains of *Candida* and *Torulopsis*, Dr. J. C. Gower for sorting these data by computer, and for his advice with Dr. R. M. Needham on handling the numbers, and Prof. S. R. Elsden for his valuable criticisms.

MECHANOCHEMICAL ENGINES

By DR. I. Z. STEINBERG, DR. A. OPLATKA and PROF. A. KATCHALSKY
The Weizmann Institute of Science, Rehovot, Israel

THE isothermal conversion of chemical metabolic energy into mechanical work underlies the motility of all living organisms. During the past two decades, synthetic models have been developed which have made it possible to investigate mechanochemical conversion on simpler systems amenable to a fuller theoretical interpretation. Polyelectrolyte fibres played a special part in this respect, since with them reversible contraction and relaxation could be easily obtained, for example, by simply changing the *p*H of the medium[1]. However, the operation of these synthetic fibres was generally slow and of poor reproducibility, so that attention has of late been directed to other materials, such as reconstituted collagen fibres, which undergo reversible 'chemical melting and crystallization' with concomitant contraction and relaxation. Rapid, reversible and reproducible contraction of partially cross-linked collagen can be obtained by treating the fibres with various reagents, such as aqueous solutions of lithium bromide, potassium thiocyanate or urea[2]. The contraction is strongly marked—at zero force a fibre would contract to about half its length, or if a force were applied, the fibre would lift a weight several thousand times its own.

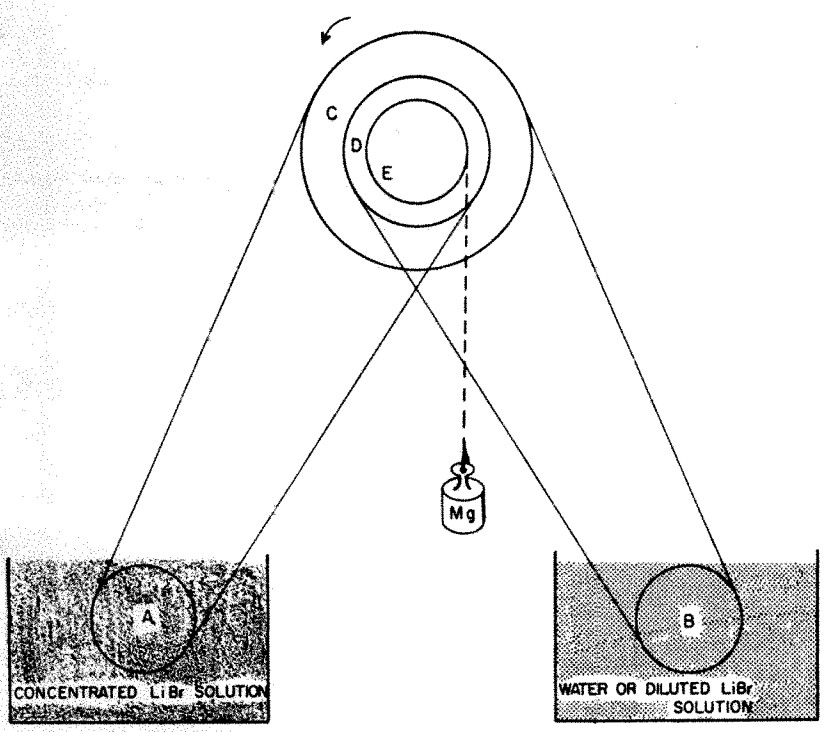

Fig. 1

Washing the fibres with water or a dilute solution reverses the process and leads to recrystallization and elongation, or relaxation, of the collagen. The contraction–relaxation cycle can be repeated many times by bringing the fibre alternately into contact with two liquids, such as a dilute and a concentrated solution of lithium bromide. During this process the solutions are mixed and the net mechanical work obtained in such a cyclic operation results from the free energy of mixing of these solutions. It was considered to be of interest to utilize this alternating contraction–relaxation process of contractile fibres in the construction of a continuously operating engine in which a difference in chemical potential would produce mechanical work in a direct manner. Such an engine should be capable of automatically carrying out the transfer of the fibre from one environment to another. Furthermore, rotary motion seemed to be preferable as the mechanical output of the engine. This article describes some isothermal mechanochemical engines which convert chemical energy directly into a continuous, self-regulating, rotary mechanical performance.

Fig. 1 shows the principle underlying the construction of a family of engines built in this Institute[3].

A closed loop of collagen fibre is wound around the pulleys as indicated in the drawing. When pulley A is dipped into a strong salt solution (such as 8–10 M aqueous lithium bromide) the collagen bathing in the solution contracts and exerts equal forces on the rims of pulleys C and D, which are rigidly connected. Since the radius of C is larger than that of D, a net rotary moment will act on the compound pulley C–D and will cause a counter-clockwise rotation. The rotation will bring a new part of the collagen belt into the salt solution, which reproduces the same effect. It should be noted that at each revolution of the pulley C–D, a longer stretch of fibre is brought in by pulley C than is taken out by pulley D. For a steady-state operation of the engine the net length of fibre introduced by C–D into the salt solution should be counterbalanced by the contraction due to the chemical interaction of collagen with salt. Correct matching of contraction and excess length introduced by C–D is achieved by a proper choice of the radii of C and D, as will be shown later.

The reverse process occurs at pulley B, which dips into water or a dilute salt solution which washes out the salt and relaxes the collagen.

Mechanical work may be obtained by, for example, attaching a suitable weight to the end of a cotton thread wound in the proper direction around pulley E, which has a common axis with C–D. While the engine is working, salt is transferred from the concentrated solution to the dilute one. It is the free-energy change due to this transfer, and to the associated water flow, that is converted partly into the mechanical work.

A useful modification of the model shown in Fig. 1 is represented schematically in Fig. 2.

Here a closed loop of collagen fibre E passes through a salt solution in the lower bath F and through water in the upper bath G. The transmission disks, A and B, rigidly coupled with the main wheels C and D, respectively, are connected by a loop of an inelastic string (a cotton fibre in the machine constructed). As the lower bath is filled up with salt solution, a contractile force develops in the part of the collagen which is immersed in the solution. This force acts on wheels C and D and tends to rotate the former counter-clockwise and the latter in a clockwise direction. The system of wheels will rotate in the direction of the algebraic sum of the moments acting on C and D. For the sake of simplicity, let us assume transmission disks A and B to be of equal radius. If wheel C has a larger radius than that of D, the wheels in the salt bath will turn counter-clockwise. Considerations similar to those presented for the model described in Fig. 1 dictate the choice of the ratio of the various pulleys in relation to the extent of contraction of the fibre.

Fig. 3 is a photograph of an experimental engine of the type drawn in Fig. 2. The upper two pairs of wheels were added to facilitate the entrance of the collagen loop into the water bath.

Let us now consider the mechanical work performed by a unit mass of collagen fibre when it undergoes a complete cycle in the engine depicted in Fig. 2. The specific length, l, that is, the length per unit mass of the collagen fibre, depends on the extent of the interaction of the fibre with salt as well as on the acting force. Hence, l will assume different values at different points on the belt. For the sake of simplicity we shall make several assumptions:

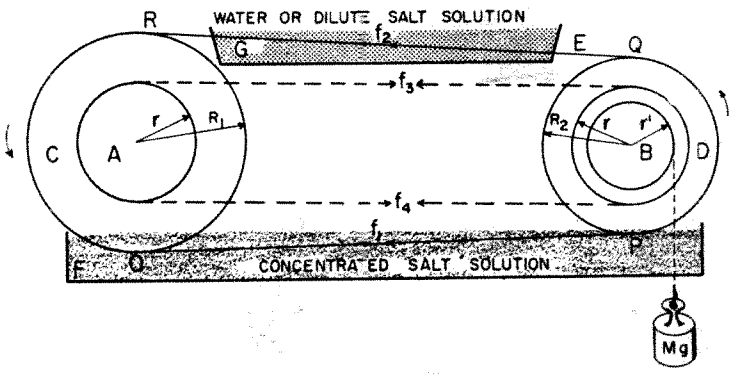

Fig. 2

(*a*) That the force f_1 in bath F between points O and P is constant. Similarly, the force f_2 in bath G between points Q and R is constant.

(*b*) The baths will be regarded as long enough to allow the collagen at P to assume an equilibrium length $\bar{l}_P$ corresponding to the salt concentration in the bath and to the force f_1. Similarly, the passage of the fibre through the water bath will allow the specific length of the collagen at point R to be the corresponding equilibrium length $\bar{l}_R$.

(*c*) We shall finally assume that the fibre firmly adheres to the pulley D between the points P and Q, the specific length remaining there at the value $\bar{l}_P$. A similar assumption is made for the interval R–O where the specific length retains a constant value $\bar{l}_R$.

The mechanical work performed by the engine when a point on the collagen fibre makes a full cycle is given by:

$$W = 2\pi r' \nu M g \tag{1}$$

where r' is the radius of the wheel carrying the mass M lifted by the machine, ν is the corresponding number of revolutions of wheel B, and g is the gravitational constant. Since B and D are rigidly coupled, the wheel D will transfer at the same time a mass m of collagen:

$$m = \frac{2\pi R_2 \nu}{\bar{l}_P} \tag{2}$$

Hence the mechanical work performed per unit mass of collagen transferred, $\overline{W}$, is:

$$\overline{W} = \frac{2\pi r' \nu M g}{2\pi R_2 \nu \bar{l}_P} = M g \bar{l}_P \frac{r'}{R_2} \tag{3}$$

When the machine runs at a constant velocity, the net moment acting on each of the pulleys A–C and B–D is evidently zero, that is (neglecting frictional forces at the bearings and in the solutions):

$$R_1(f_1 - f_2) + r(f_3 - f_4) = 0$$
$$R_2(f_1 - f_2) + r(r_3 - f_4) + r'Mg = 0$$

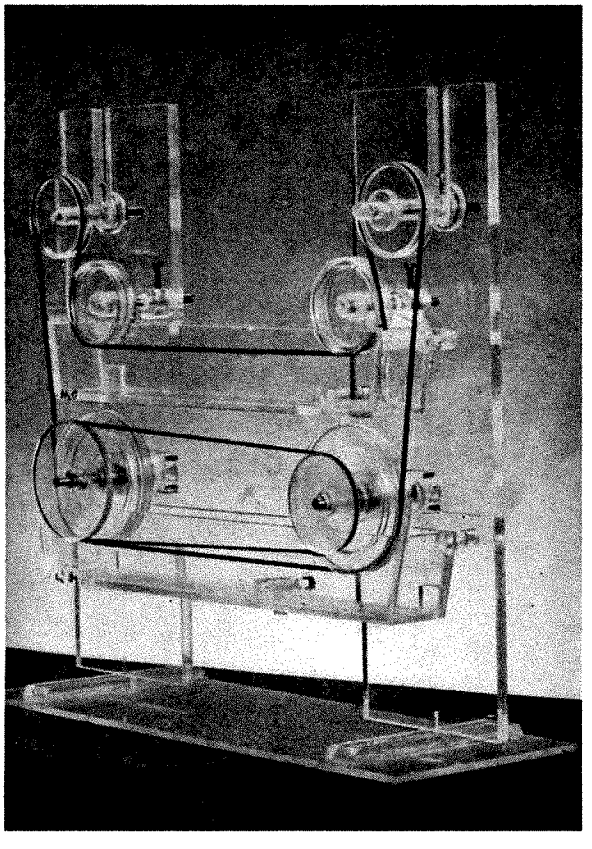

Fig. 3

or

$$(R_1 - R_2)(f_1 - f_2) = r'Mg \tag{4}$$

Introducing equation (4) into equation (3), we get:

$$\overline{W} = \frac{R_1 - R_2}{R_2}(f_1 - f_2)\bar{l}_P \tag{5}$$

For an engine to operate steadily, the amount of collagen entering the salt bath for each rotation of wheel C should equal the amount which leaves the bath with wheel D, or:

$$\frac{2\pi R_1}{\bar{l}_R} = \frac{2\pi R_2}{\bar{l}_P}$$

which dictates the choice of the ratio of the radii:

$$\frac{R_1}{R_2} = \frac{\bar{l}_R}{\bar{l}_P} \tag{6}$$

Introducing equation (6) into equation (5), we obtain the result:

$$\overline{W} = (f_1 - f_2)(\bar{l}_R - \bar{l}_P) \tag{7}$$

For mechanical work to be gained, both terms on the right-hand side of equation (7) should have the same sign.

The efficiency η of the conversion of chemical into mechanical energy is given by:

$$\eta = \frac{\overline{W}}{\Delta n_s \Delta\mu_s + \Delta n_w \Delta\mu_w} = \frac{(f_1 - f_2)(\bar{l}_R - \bar{l}_P)}{\Delta n_s \Delta\mu_s + \Delta n_w \Delta\mu_w} \tag{8}$$

where Δn_s and Δn_w are the number of moles of salt and water, respectively, transported by a unit mass of collagen from the concentrated to the dilute salt solution, whereas $\Delta\mu_s$ and $\Delta\mu_w$ are the corresponding differences in the chemical potentials in the two baths. Since we have neglected frictional losses in the derivation of equations (7) and (8), the real values of W and of η should evidently be smaller than those given by the last two equations.

The mechanical power and the chemical free energy involved have been examined in an engine of the type shown in Fig. 2. The fibre used was a formaldehyde-tanned 4/0 reconstituted collagen tape, which has been pretreated with an 11·0 M lithium bromide solution at 60° C for 10 min and then washed in water and dried in air overnight. The weight of the fibre was 44 mg. The machine had the following dimensions: the distance between the axes of the wheels was 20·0 cm; R_1 = 3·44 cm; R_2 = 3·05 cm; R_A = 3·55 cm; r = 3·15 cm. 11·25 M and 0·3 M lithium bromide solutions respectively were pumped through split tubes which served as the two baths. The mechanical power output was measured by means of a friction belt on an auxiliary wheel coupled to the machine. The measurements were carried out until the concentration of the concentrated solution changed by about 10 per cent. During this period (about 1 h) both the power and the chemical flows were practically constant. At a temperature of 23° C, wheel B made 40 r.p.m. under zero load. The maximum power obtained was about 0·03 W/g collagen. This value is practically identical with the maximum power, per g contractile proteins, of the sartorius muscle in the frog (calculated from the data of ref. 4).

Pryor[5] described a device in which a wheel with spokes made of collagen fibres was suspended in a trough filled to the level of the wheel axle with a concentrated solution of lithium bromide and above that with water. Contraction of the lower spokes placed the wheel in imbalance, thus effecting rotation. That device produced a complete rotation of the wheel in about 20 min. Obviously, spontaneous degradation of the chemical free energy due to diffusion was an inherent defect in that apparatus.

It is most probable that the machines described can be operated by other fibres that undergo reversible contractions and relaxations under the influence of suitable reagents. Furthermore, a continuously working thermal engine of the same design could be envisaged with

materials which develop varying contractile forces with changes in temperature. For example, rubber strips could replace the collagen fibres and two compartments at different temperatures could replace the chemical baths.

We thank Mr. M. Feld for his excellent work in the construction and development of mechanochemical engines; the Ethicon Co., Somerville, New Jersey, for the supply of collagen fibres and help in various stages of our research; Mr. J. Yonath for helpful discussions and Dr. G. Goldman for providing his preliminary experimental results before publication.

This research was sponsored by the Air Force Office of Scientific Research under a contract through the European Office of Aerospace Research.

SCIENCE IN CHEMICAL ENGINEERING*

By PROF. P. V. DANCKWERTS

President, Institution of Chemical Engineers

CHEMICAL engineering was not originally science-based in the same sense as electrical engineering. Although the chemical industry was firmly based on the science of chemistry, the role of the chemical engineer was originally merely to provide vessels, pipes, pumps and so on to enable a reaction to be carried out under the conditions specified by the chemist. It is true that there are early examples of where the engineering interacted with and influenced the process—for example, the lead-chamber sulphuric acid process, the Solvay ammonia-soda process and the Haber-Bosch ammonia synthesis. In general, however, the chemical engineer had little influence on the process, and there was very little science involved in chemical engineering. The most difficult part of the job was the choice of the right materials of construction—but until quite recently science has been of little help in this respect.

The type of chemical engineer I have just described—typical, perhaps, of the year 1900—has given way to someone who occupies a very different position. The scientific and unspecialized nature of the training of the chemical engineer fits him for employment in many industries apart from the chemical industry—for example, combustion engineering, food processing and extraction metallurgy. The proportion of chemical engineers employed in non-chemical industries in Britain has risen steadily in the past decade, and now amounts to about 25 per cent. This wider dissemination of the philosophy of chemical engineering is an important feature of the development of the profession, and is likely to be of great benefit to certain industries which have been somewhat isolated from the main stream of technological development.

I shall use the phrase "chemical engineering science" to mean the science deployed by chemical engineers in their various activities. It is clear that the chemical engineer does not himself always have to develop scientific methods for solving the problems which he encounters. For example, although he is professionally very deeply concerned with the properties of materials, he is not usually thought to be responsible for developing the science and technology of materials—metallurgy, corrosion, refractories, and so on. Other technologists have assumed this responsibility, which on the whole requires a different scientific background from that of the chemical engineer. Chemical engineering science is, therefore, the body of applied science developed by chemical engineers for their own purposes, in fields not covered by other branches of technology. It would be a great mistake to think of the content of chemical engineering science as permanently fixed. It is likely to alter greatly over the years in response to the changing requirements of industry and to the occasional technological 'break-through'.

The functions of chemical engineering science are mainly economic. One is the development of quantitative design procedures, so that full-scale plants can be designed by calculation, if necessary with the help of laboratory-scale experiments, but if possible without the need for expensive and time-consuming pilot-scale experiments. The more precise the design procedures which can be developed, the more precisely is it possible to optimize the design of plant, and the narrower becomes the wasteful margin of safety imposed by ignorance. There is also the need to improve the efficiency of processes and of the plant in which they are carried out—for example, to obtain a higher yield in a chemical reaction, a higher plate-efficiency in a distillation column, or a machine which will produce granular material of a more nearly uniform size. There is also the matter of true invention, leading to quite new processes and devices. Although science may not always provide the inspiration for inventions, it must usually be called in to develop them properly. Finally, there is the need to develop not only automatic but also self-optimizing processes and plants; in the chemical factory of the near future we shall have replaced not only the workman but the management by instruments.

The field of automation, incidentally, is a good example of the way in which the relative importance of different parts of the field of chemical engineering science can rapidly alter. Ten years ago most of us did not see beyond the simple feed-back control loop, and now a considerable part of the literature is concerned with much more sophisticated topics in the field of automation.

Pilot-scale experiments are of course not only expensive, but also occupy much time, and in the chemical industry it is often of vital importance to bring new processes into production quickly. The smaller the scale on which experimental work is done, the cheaper and quicker it will be. Much of chemical engineering science is therefore concerned with the problem of scaling-up. How does one design small-scale experiments which will give the information required for the design of full-scale plant? To what extent is it possible or necessary to build a true model of the plant? Is it possible to abstract some essential features and model these, while relaxing other criteria of similarity? Unfortunately, the type of plant used in industry for the sake of its efficiency or convenience is often very difficult to represent by a small-scale model. For example, in a fluidized-bed reactor we know that the effectiveness of the catalyst is likely to be influenced by the possibility that some of the reactant stream passes through the bed in bubbles, and does not come into contact with the catalyst. It is most unlikely that the effectiveness will be the same in a small model, even if we try to make all the operating parameters the same. Can we, therefore, derive any useful conclusions from observations on a small fluidized-bed reactor? In order to do so, we need a real insight into the

* Based on a draft for the Presidential Address to the Institution of Chemical Engineers, April 26, 1966.

mechanics of fluidized beds, on both the small and large scales; this may not enable us to make design predictions by means of calculations based on first principles, but without it we shall not know what experiments to carry out, or how to apply the results to design. One of the principal objectives of chemical engineering science is to provide methods for the design of experiments which will yield information of direct value to designers of processes which are too complicated to be modelled exactly or to be subjected to precise mathematical analysis.

Chemical engineering science, like other branches of science, is of course being profoundly influenced by the use of high-speed automatic computers. For one thing, the formulation of the problems is altering; no longer is it so important to be skilful in constructing conceptual models which bear an adequate resemblance to the problem under consideration and which can also be described in tractable mathematical terms. One can present the problem to a computer in a much more realistic form, and expect to get a much more accurate answer. This trend towards realistic calculation also creates a demand for more accurate knowledge of the physical behaviour of the system and is likely to make further experimental work rewarding rather than render it unnecessary. For example, trial-and-error plate-to-plate calculations for multi-component distillation equipment can now be carried out with great facility; the bottleneck in optimizing the design of such equipment lies in the limited knowledge of the factors which determine plate efficiency, and in the limited availability and accuracy of vapour-liquid equilibrium data.

In the department of physical chemistry, the laws governing chemical and phase equilibrium are among our most important tools. It is, of course, not enough to understand the principles—one must have thermodynamic data for calculation. I feel that an important field of activity for chemical engineers is the development of scientific methods for estimating thermodynamic quantities, both chemical and physical, in systems where they have not been measured.

The physical chemistry of interfaces has become of increasing interest to chemical engineers in recent years, particularly in relation to the formation and behaviour of drops, bubbles, foam, in mass-transfer equipment. In many cases we have a qualitative insight into the phenomena, but quantitative prediction is usually difficult—indeed, the profound effect of very small quantities of impurities sometimes renders it impossible to foresee the behaviour of a system even approximately. We may find that foaming is the limiting factor in the operation of a distillation column or an evaporator, or emulsification in the case of solvent extraction, and that the conventional problems of mass and heat transfer become of quite secondary importance.

Still in the department of physical chemistry, a topic of supreme importance for the chemical industry is that of catalysis. In general there seems to be a very wide gap between fundamental scientific understanding of the behaviour of heterogeneous catalysts, on one hand, and industrial practice, on the other hand.

A sub-department of chemical engineering science, sometimes called chemical reaction engineering, has grown up to deal with the design and optimization of various types of chemical reactor. The reaction kinetics themselves are usually taken as given, and attention is concentrated on such aspects as mass-transfer of reactants and products, back-mixing of reactant-streams and residence-time distribution, the control of temperature and the coalescence of liquid drops.

The next department to consider is that of fluid mechanics Many of the aspects which are of particular interest to chemical engineers are still in a state of obscurity, although promising work is in progress. Much remains to be done in the flow of liquid-gas, liquid-solid and gas-solid mixtures in pipes; the mechanics of fluidized beds; the settling of dense suspensions; the mechanics of bubbles, froths and foams; the flow of non-Newtonian fluids; and the mixing of fluids. The industrial importance of all these fields is not in doubt, yet I have the impression that real progress is extremely slow.

Turning to transfer processes, one finds a similar situation. Industrial mass-transfer equipment, for example, is designed to be effective, not to be simple for chemical engineering scientists to analyse. It is still not possible (in spite of the recent concentrated research programme of the American Institute of Chemical Engineers) to predict plate-efficiencies of distillation column for novel mixtures with any confidence. Much of the published work in this field has been of rather academic interest, and there are many problems of outstanding practical importance still to be solved.

The department of logic and control theory is perhaps the most active part of chemical engineering science these days. The subjects dealt with include the application of computers to standard design procedure (for example, the calculation of the number of equilibrium stages required in a distillation column); the development of procedures for optimizing the design of single items of plant and of complete factories; methods of feed-back and feed-forward control, control by on-line digital computer, and optimal and adaptive control systems. It is in these directions that the most striking and rapid developments in the chemical and petroleum industries are coming about at the moment, and the department is naturally one which is attracting a great deal of attention from chemical engineering scientists both in industry and in academic life. In fact, it may be claiming more than its fair share of attention. It brings some of the glamour of the space-age to the down-to-earth job of the chemical engineer, but no amount of automation will make a success of a process which is not sound from the engineering point of view.

The last department I should like to mention is the design of chemical plant and machinery, in the structural and mechanical sense. The influence of science in this important field seems to be extremely small, in any event in Britain. It is probably a weakness of the British system that scientifically trained chemical engineers tend to be process designers rather than designers of equipment and machinery, while scientifically trained mechanical engineers have too little insight into chemical engineering operations to make a great contribution to the development of equipment and machinery. It is true that there are certain fields, such as the design of pressure vessels, where scientific method has had an influence; and there are others, such as the design of pumps, where the chemical engineer has benefited from developments in general engineering. On the whole, however, the design of chemical engineering equipment and machinery as such seems to have attracted relatively little scientific attention.

There are some welcome signs that chemical engineering science is moving away from its excessively physical standpoint of the past few decades, to one in which more interest is taken in chemical phenomena. In the universities, both in teaching and in research, there may be advantages in placing more emphasis on applied chemistry and the chemical phenomena which form the basis of the chemical industry. The McLeod Report exposed the lack of research in chemical technology in our universities, and recently certain steps have been taken which will help to remedy this situation. As for teaching, I am sure that if we could turn out a chemical engineering graduate with a much deeper insight into chemical phenomena than we do at the moment, he would prove to be invaluable in process development work in the chemical industry. I must admit, however, that within the limits of our present university course, we can do little in this direction without a reduction in the attention paid to other topics. Perhaps the solution is to have degree courses which vary considerably in flavour from one university to another—a possibility envisaged in the *Scheme for a Degree Course*

which the Institution of Chemical Engineers has recently produced.

Surveying the field of chemical engineering science as a whole, therefore, there are certain fields, such as chemical thermodynamics and the logical-mathematical field, which can be developed rigorously from known principles. There are others, such as multiphase fluid mechanics and the technology of granular materials, which are of great technical importance but which are much less highly developed in principle, and require a combination of physical insight and experimental flair if progress is to be made. I feel that chemical engineering science should not become exclusively identified with the 'rigorous' subjects, and that we should be ready to use science to solve any of the problems of chemical engineering, however ill-formulated they may be. Those of us who work in universities or research institutes, and who claim to be chemical engineers, should be guided in our work by the genuine difficulties and economic requirements of industry, and not develop subjects for the sake of their intellectual interest alone. There is, I believe, sufficient intellectual interest in identifying the real problems and formulating them and trying to solve them (if only partially).

NEWS AND VIEWS

New Members of the National Academy of Engineering

THE following have been elected to membership of the academy: H. JULIAN ALLEN, director, Ames Research Centre, National Aeronautics and Space Administration; L. L. BERANEK, president, Bolt, Beranek and Newman, Incorporated; PROF. D. S. BERRY, Department of Civil Engineering, Northwestern University; H. G. BUSIGNIES, general technical director, International Telephone and Telegraph Corporation; PROF. A. CASAGRANDE, professor of soil mechanics and foundation engineering, Harvard University; PROF. T. H. CHILTON, visiting professor, University of Virginia; E. E. DAVID, JUN., executive director, Communications Systems Research Division, Bell Telephone Laboratories, Incorporated; PROF. H. E. EDGERTON, Department of Electrical Engineering, Massachusetts Institute of Technology; J. B. FISK, president, Bell Telephone Laboratories, Incorporated; E. G. FUBINI, vice-president for research and development, International Business Machines Corporation; W. M. HAWKINS, assistant secretary for research and development, United States Department of the Army; W. R. HIBBARD, director, Bureau of Mines, United States Department of the Interior; A. A. H. KEIL, technical director, David Taylor Model Basin, United States Department of the Navy; R. KOMPFNER, associate executive director of research, Communications Sciences Division, Bell Telephone Laboratories, Incorporated; H. LANDSBERG, director, Environmental Data Service, United States Department of Commerce; PROF. W. K. LEWIS, professor emeritus and honorary lecturer, Massachusetts Institute of Technology; F. K. MCCUNE, vice-president, Business Studies Service, General Electric Company; PROF. R. D. MINDLIN, professor of civil engineering, Columbia University; B. M. OLIVER, vice-president for research and development, Hewlett-Packard Corporation; E. R. PIORE, vice-president and chief scientist, International Business Machines Corporation; C. F. PRUTTON, director, FMC Corporation; J. A. RAJCHMAN, director, Computer Research Laboratory, RCA Laboratories, Radio Corporation of America; PROF. H. ROUSE, director, Institute of Hydraulic Research, University of Iowa; J. W. SIMPSON, vice-president and general manager, Electric Utility Group, Westinghouse Electric Corporation; PROF. V. SUOMI, Department of Meteorology and Soils, University of Wisconsin; PROF. O. G. VILLARD, JUN., professor of electrical engineering and director of Radioscience Laboratory, Stanford University; J. B. WIESNER, dean of science, Massachusetts Institute of Technology.

Dr. Kaysen to head Institute of Advanced Study

WHEN Dr. J. Robert Oppenheimer retires on July 1 after 19 years as director of the Institute for Advanced Study at Princeton, New Jersey, he will be succeeded by Dr. Carl Kaysen. Kaysen is professor of political economy at Harvard University and since 1961 has been associate dean of the Harvard Graduate School of Public Administration.

Dr. Kaysen received an A.B. in 1940 from the University of Pennsylvania and an A.M. in economics in 1947 from Harvard. He was a Junior Fellow of Harvard's Society of Fellows from 1947 until 1950. He received a Ph.D. from Harvard in 1954 and was appointed a full professor in 1957. In 1956 he was a visiting Fulbright professor at the London School of Economics and a Guggenheim Foundation fellow. From 1961 to 1963 he was on leave of absence from Harvard to serve as President Kennedy's Deputy Special Assistant for National Security Affairs. As an adviser to both Kennedy and Johnson, his work has centred on problems of nuclear disarmament, the military budget, and planning; he has served as a consultant to the Departments of Defense and Justice.

Oppenheimer, now 61, has been head of the Institute since 1947, after being in charge of the Los Alamos atomic bomb project during the Second World War. He will remain at Princeton as senior professor of theoretical physics, the post once held by Albert Einstein.

The fact that Kaysen is a social scientist is not expected to change the emphasis of the Institute. His three predecessors include Abraham Flexner, an educator and one of the founders of the Institute, who was director from 1930 to 1939. Frank Aydelotte, president of Swarthmore College for 19 years, directed the Institute from 1939 to 1947, when Oppenheimer was appointed.

The permanent faculty consists of thirteen research workers in historical studies, ten mathematicians, and five natural scientists. In addition, about a hundred temporary members are invited for one or two years.

Defence Studies in the United Kingdom

IN a written answer in the House of Commons on March 2 regarding the development of higher defence studies in the United Kingdom, the Secretary of State for Defence, Mr. Healey, stated that one of the primary objectives of the Government was to stimulate the interest of the universities in this field, and to encourage them to play a more active part as well as to foster general intellectual awareness of the problems of defence. As already announced, the Government proposed to award up to six fellowships annually to enable senior serving officers to study or carry out research in the atmosphere of a university. The Fellows themselves were expected to gain substantially. The Services and Ministry would have the benefit of the greater capacity for analysis which the students would acquire, and the universities would benefit from contact with experienced students of defence. The Government has also announced its intention of creating, at public expense, in each of a few selected universities,

an additional post of lecturer or senior lecturer in an existing faculty to specialize in the defence aspects of its discipline. Mr. Healey did not envisage initially any restrictions as to the faculties in which these posts should be set up. Teachers in any of the social or physical sciences or in technology with an interest in defence problems would be encouraged to specialize in their study. Eventually it was hoped that defence studies would emerge as a discipline in its own right in the universities concerned. The Defence White Paper also referred to the organization of short, intra-mural courses in the widest possible variety of subjects. Some of these would be organized in collaboration with the lecturers specially appointed under the arrangements mentioned. Some would be concerned with specific subjects of present and impending interest in the defence field. Others would deal with the techniques of management, and it was hoped to collaborate with the business management schools recently established at London and Manchester. These proposals represented a modest step forward on an experimental basis and at the same time the Government intended to create, within the Ministry of Defence, an organization to undertake, in an atmosphere free from day-to-day problems, research and long-range planning in the defence field. This organization would be designed to enable Britain to carry out research and to attempt to identify problems before they arose and to make available the results of the various studies to all those concerned with the day-to-day formulation and conduct of British defence policy. This activity would be carried on in association with the new university posts of lecturer or senior lecturer which were to be created, as well as with other universities or research centres which could help. Close liaison would also be maintained with Government departments concerned.

The Countryside and Leisure

THE White Paper, *Leisure in the Countryside: England and Wales*, amplifies slightly the statement on Countryside Parks which the Minister of Land and Natural Resources made to the 'Countryside in 1970' Conference in November 1965. However, it does not meet the real criticism of his proposals (Pp. 15. Cmnd. 2928. London: H.M.S.O. 1*s*. 6*d*. net). Parliament is to be invited to give elected local bodies the powers and the financial help they need to ensure that the resources of the countryside match the needs of the nation and to convert the National Parks Commission into a Countryside Commission. This Commission will be responsible for promoting and co-ordinating action and advising the Government on the measures needed for full enjoyment of the countryside and protecting its natural beauty. While reconnaissance, planning and research are proposed locally and nationally pending the introduction of an appropriate Bill, there are no proposals to provide the Commission itself and the Park authorities with either the financial resources or the powers they need for effective discharge even of their past responsibilities. On administration, the Government is content to hope that for Parks covering more than one county, the planning authorities concerned will consider very seriously the possibility of a change to joint planning boards, although the Government will consider exercising its power to revoke existing arrangements if further experience shows this to be required. For the future there will be a 75 per cent grant towards appropriate items of current expenditure and towards loan charges in respect both of National Parks and Areas of Outstanding Natural Beauty, and it is also proposed that an Exchequer grant at the rate of 75 per cent should be payable towards the additional administrative expenses of National Park Planning Authorities in creating new facilities or improving the landscape. The main instrument for creating County Parks would be the County Councils, and grant will be payable on approved expenditure. Other proposals relate to access to water, both gathering grounds and rivers and canals, to open country, to trees and woodlands. A reference to long-distance routes, however, reads strangely in the light of the comment in the National Parks Commission that progress here has been limited by the financial restrictions the Government itself imposed on the Commission.

Problems of Peace

IN his 1965 Alex Wood Memorial Lecture, *Dilemmas of Peacemaking*, Prof. E. G. Rupp concentrates, like R. Ullmann, on what are called 'East–West relations', and from a Christian and historical point of view (Pp. 10. New Malden, Surrey: The Fellowship for Reconciliation, 1965. 2*s*.). Indeed, Prof. Rupp describes his work as an afterthought to Ullmann's pamphlet *Dilemmas of a Peacemaker*. The experience of the Christian Peace Movement has been to discover men of great understanding, Christian spirit and integrity, and with more common ground than would have been conceivable if the confrontation between East and West had not been attempted. The confrontation has led to other positive gains, such as the realization of the deep underlying appreciation of the futility and evil of war, the dissolution of the problem of peace into its component parts and the demonstration of its indissoluble links with social justice. Prof. Rupp emphasizes the risk of misunderstandings through the use of such terms as peace, democracy and freedom when different meanings are attached to them, and he urges that the response to appeals to renounce war must be supported with intelligence and determination by millions. He agrees with Lincoln that these great concepts derive their meaning not from intellectual debate and discussion but from life itself.

New NASA Tracking Antenna

A NEW automatic tracking antenna, 210 ft. in diameter, was dedicated on April 29 at the Goldstone Communications Complex in the Mojave Desert, California. When it becomes operational in May or June it will be used by the National Aeronautics and Space Administration's Deep Space Network for tracking unmanned vehicles in space. The new antenna just completed by the Jet Propulsion Laboratory is a parabolic aluminium dish measuring 234 ft. from the desert floor to the peak of its apex. The entire structure, including the pedestal, weighs 8,000 tons. Rohr Corporation of San Diego, the prime antenna contractor, and dozens of other firms have taken 6 years to complete this 14 million dollar project.

The enormous size and nearly perfect contour of the "210" gives it a greater range and sensitivity than even larger antennae now in operation, such as the 250 ft. at Jodrell Bank. Its 715-ft. circumference forms a circle with an accuracy within 0·05 in., and is contoured to an accuracy of less than 0·25 in.

The Goldstone station is the primary station of the Deep Space Network, with other stations at Johannesburg, South Africa; Woomera and Canberra, Australia; and Madrid, Spain. This network is used only for tracking and two-way communication with unmanned vehicles, such as the *Pioneer* and *Ranger* series and the Venus and Mars probes of the *Mariner* spacecraft. It is distinct from the other NASA networks such as the Manned Space Flight Network, which tracks the *Gemini* and *Apollo* spacecraft, and the Scientific Satellite Network, which tracks Earth-orbiting scientific, meteorological and communications satellites.

NASA plans to use the "210" for continued tracking of the *Pioneer VI* spacecraft now in orbit around the Sun. With the 85-ft. antennae at present being used, the *Pioneer* could be followed for 6 months, but the more sensitive "210" should increase the useful life of the spacecraft to 14 months.

The reflector and its supporting structure rotate on a hydrostatic bearing. The base of the antenna is a pedestal

housing the control room, machinery and equipment rooms and the communications systems. It is anticipated that antennae the size of the "210" will be constructed eventually at other sites of the Deep Space Network.

Electrical Biology Laboratory

A LABORATORY for biological research for the electrical industry has been established by the Central Electricity Generating Board at Leatherhead, Surrey. The Laboratory was opened officially on May 6, 1966, by Sir Cyril Hinshelwood. It is intended to be a centre for the biological research of all kinds carried out by electricity authorities in all parts of Britain. Among the problems within the scope of the new Laboratory are the study of the growth of barnacles and mussels in power station cooling water. Mussels can detract from the operating efficiency by lodging in condenser tubes, thus causing corrosion. The same tubes are ideally suitable for the growth of many other marine organisms, which must be eliminated without, at the same time, so contaminating the water as to make it a public hazard. The Laboratory is also concerned with biological problems arising from the increased temperature of water discharged from power stations. The facilities of the Laboratory will include special tank rooms for the study of freshwater invertebrates. It will have X-ray machines which will, in particular, be able to study the effect of temperature on the shipworm *Teredo*—a pest of wooden marine structures. It is also intended to study the biological problems arising from the use of pulverized fuel ash in the reclamation of agricultural land.

Modern History

IN his presidential address to the Diamond Jubilee Conference of the Historical Association, Geoffrey Barraclough, Fellow of St. John's College, Cambridge, stressed that historians must offer the general public something more than technical controversies if they wished to compete against "the attractions of modern science".

Speaking on the subject "History and the Common Man", Barraclough said that the study of history has lost its sense of purpose and is suffering from what he termed a *malaise*; to the ordinary educated mathematician, nuclear physicist, and natural scientist, "history is a form of entertainment; . . . relaxation for the intelligent scientist or technologist who is a cut above the telly and does not take to novels". He added that there was "a sharp cleavage between history written for the public, which is not scholarly, and scholarly history which is not read by the public".

The two aspects of current historical teaching and research that Barraclough felt must change are its lack of relevance to present events and its fundamental postulate that history is the key to the explanation of events. He deplored the fact that the teaching of history was only slowly changing from the study of minute investigations of obscure details of British history to leave more time for the broader issues of European and world history.

Barraclough strongly attacked the Germanic approach that searched for the causes and motivations of events rather than their consequences. He noted that the Danish theologian Kierkegaard said that history should concern itself with results, while motives and intentions are the business of ethics. Barraclough expressed the belief that this historical guesswork is being replaced by a more scientific approach to history, in spite of a "suicide squad fighting a stubborn rearguard action". This means, he added, that "historians, at last, are breaking away from their vain pre-occupation with motives and causes and surmise, and getting down to facts".

It will be interesting to see if this hopeful prediction is fulfilled, and, if so, whether history will become less entertaining in the process.

University News: Glasgow

THE following have been appointed to chairs: H. B. Sutherland (civil engineering); Dr. I. A. Boyd (physiology); Dr. R. M. S. Smellie (biochemistry).

London

SIR THOMAS CREED, principal of Queen Mary College, has been elected vice-chancellor as from September 1, for the university year 1966–67. Prof. C. T. Ingold, of Birkbeck College, has been appointed deputy vice-chancellor as from September 1 for the university year 1966–67. The title of professor has been conferred on the following: Dr. R. H. Gorrill (bacteriology, in respect of his post at Guy's Hospital Medical School); Dr. E. Jean Hanson (biology, in respect of her post at King's College); Dr. C. W. Kilmister (mathematics, in respect of his post at King's College).

Announcements

DR. V. BUSH was awarded the first Founders' Medal of the National Academy of Engineering during the second annual meeting of the National Academy of Engineering on April 27. The Founders' Medal was established in April 1965 to honour outstanding contributions by an engineer both to his profession and to society.

PROF. B. EDLÉN of Lund has been awarded the Mees Medal of the Optical Society of America for distinguished work over a period of more than thirty-five years on the light emitted by the vapours of highly ionized elements.

A SYMPOSIUM on "Simulation Techniques and Languages" will be held in Brunel College during May 10–11. Further information can be obtained from the Academic Registrar, Brunel College, Woodlands Avenue, Acton, London, W.3.

THE second international congress on "Hormonal Steroids" will be held in the University of Milan during May 23–28. Further information can be obtained from Dr. L. Martini, Istituto di Farmacologia, Via Andrea del Sarto 21, Milan.

A SHORT course on "High Temperature Resistant Polymers" will be held at the Bradford Institute of Technology during May 13–14. Further information can be obtained from the Registrar, Bradford Institute of Technology, Bradford 7.

THE fifth international congress of the precast concrete industry will be held in London during May 21–27. Further information can be obtained from the Organizing Secretary of the Congress, Terminal House, Grosvenor Gardens, London, S.W.1.

THE third annual national colloquium on "Information Retrieval" will be held in the University of Pennsylvania during May 12–13. Further information can be obtained from A. W. Speakman, E. I. du Pont Company, Centre Road Building, Wilmington, Delaware.

A SYMPOSIUM on "Physico-Chemical Processes in Mixed Aqueous Solvents" will be held at Bradford Institute of Technology during May 23–24. Further information can be obtained from Dr. F. Franks, Department of Chemical Technology, Bradford Institute of Technology, Bradford 7.

A COURSE on "Cancer Chemotherapy" will be held in the University of Texas during May 9–21. Further information can be obtained from the Division of Continuing Education, University of Texas Graduate School of Biomedical Sciences at Houston, 102 Jesse Jones Library Building, Texas Medical Center, Houston.

THE sixth international symposium on "Condensation Nuclei" will be held in Albany, New York, and University Park, Pennsylvania, during May 9–14. Further information can be obtained from the chairman of the Organizing Committee, Office of the Director, Atmospheric Sciences Research Center, State University of New York, Post Office Box 7112, Albany, New York.

PLANS FOR HIGHER EDUCATION

IN opening a debate on technical education in the House of Commons on March 3, Mr. David Price drew attention to the increase in the number of students attending sandwich courses. This had risen from 4,000 in 1956 to 22,000 in 1964, and the number of day releases had risen by 196,000 to 574,000 in the same period. The number of students taking advanced courses leading to recognized qualifications at grant-aided establishments had risen from 90,000 in 1958 to 158,000 in 1964. After asking for a much greater breakdown of the figures given in the National Plan, Mr. Price urged the need for management studies in technical colleges. He thought there should be, first, a general type of course aimed especially at the established manager whose educational background might be poor; secondly, he recommended courses to keep current management in touch with new management thinking and techniques; and, thirdly, courses giving instruction in particular techniques. Sir Edward Boyle hoped that the Government would make every effort to keep the figures given in the National Plan suitably up to date, and thought there was probably a need in the new business schools for a good 2-year postgraduate university course in business education of a high intellectual level, though it should not be too academic.

In replying on the debate, the then Minister of State, Department of Education and Science, Mr. R. E. Prentice, said the National Plan hoped by 1970 to achieve a total of 70,000 students taking higher education courses compared with the figure of 50,000 recommended in the Robbins Report for 1973. Some 5,000 students were taking more specialized courses in management and about 8,000 were taking other professional examinations which included management as part of the course. In November 1964, about 276,000 people were getting day release, about 31 per cent of the boys and 7 per cent of the girls. The programme for 1966–67 was to cost £27 million and this would also be the figure for the 1967–68 programme. The National Advisory Council on Education in Industry and Commerce had been making four relevant studies; a study into the size of classes; another into buildings; one into the administrative methods of procedures; and a study of the organization of courses. These were at different stages, but the first study was complete and the report was being discussed with the local authority associations and others concerned. The position would also be improved by the raising of the school-leaving age in the 1970's, the impact of the Industrial Training Act, the expansion of the system of further education and the expansion and improvement of the youth employment service. In a written answer in the House of Commons on March 8, the Minister of Housing and Local Government, Mr. R. Crossman, stated that new arrangements were urgently needed to give an impetus to research in the environmental field. The task of reshaping existing towns, building new cities and meeting the needs of a fast-growing, mobile population demanded a vigorous, comprehensive and sustained programme of research. The failure in the past to sponsor research in this field meant that the data needed for sound policy decisions were lacking. It had been decided, therefore, to establish a Centre for Environmental Studies where practitioners and research workers, both at home and abroad, could discuss problems and settle research needs. The Centre would also be an important channel through which research contracts could be placed with universities and institutes. The Centre would be established as an independent educational trust. It was intended that it should be financed partly out of money voted by Parliament and partly from outside sources, and the Ford Foundation had agreed to make a substantial donation to the Centre over the next 5 years. Lord Llewelyn-Davies, professor of architecture in the University of London, had accepted an invitation to become chairman of the Governing Body of the Centre.

On March 9, the Prime Minister announced in the House of Commons that after careful examination of the issues involved the Government proposed that the closed period for public records should be reduced from 50 to 30 years. In reaching this conclusion they had had full regard to the recommendation of the Advisory Council on Public Records that the period should be reduced only to 40 years. The Council had found it difficult to decide between 40 and 35 years and had coupled its recommendation in favour of a reduction with a further recommendation that scholars undertaking research relating to matters falling within the period should have more liberal access to official records, including Cabinet records. The Government concluded, however, that a clean-cut closed period was to be preferred and that the period of 30 years would be reasonable. While the Leader of the Opposition agreed that a specific closed period was preferable in principle, he was not satisfied that reduction to 30 years was justified, mainly because of possible embarrassment to politicians and civil servants. The Government, however, did not think that the risk was significant.

EDUCATION AND THE AVIATION ESTABLISHMENTS

IN December 1964 the Electronics Research Council established a working party, under the chairmanship of Sir Nevill Mott, to examine the educational role of the Ministry of Aviation's establishments. Previously the Council's Working Party on Solid State Devices had recommended that the functions of the Ministry's establishments should be reviewed in order to determine what aspects of the special knowledge of their scientific staff could possibly be made available to students in higher education.

Obviously the establishments have much to offer in physics, electronics and related subjects, and the talents of the staff could be made available through secondment to universities and through students working at the establishments. The working party was therefore also asked to examine and consider the role of the universities in ensuring that students receive education which fits them for work in research, development and production in the subjects mentioned.

The earlier working party had also concluded that the establishments could—and should—play a greater part in helping civil developments in the electronics industry. It had recommended, in particular, that the possibility should be explored of establishing viable applied research units at selected universities. Such units, it was hoped, would provide incentives and opportunities for a few university departments to contribute in the field of solid-state devices, and would encourage students and post-graduates to make careers in applying solid-state physics to industry.

The working party surveyed the present position in the United Kingdom and at the same time compared it with the contribution which such establishment staff make to formal teaching in The Netherlands. It was impressed by the educational effort already made within the present mandates, and it concludes in its report, entitled *The Educational Role of the Ministry of Aviation Establishments**, that, as regards general scientific education, some encouragement and the removal of certain obstacles are all that are required.

On the other hand, as regards training which leads to design and development, the position is less satisfactory and it is here that the main responsibility of the establishments lies. The working party recommends that any establishment concerned with research and development in a given branch of technology should be encouraged to accept certain responsibilities for advanced training in this field and for seeing that educational potential resulting from its own work is properly utilized. This teaching mandate should be exercised not only as already in sandwich courses but also in postgraduate training in technology, and occasional teaching in postgraduate courses at the universities. To this end, the working party recommends that universities should be encouraged to offer selected members of establishment staffs part-time teaching positions with responsibilities particularly for postgraduate teaching similar to those in Holland.

The working party also believes that university and technical college staff should be encouraged to use research facilities in establishments and given in establishment programmes. Furthermore, it considers that the Ministry of Aviation should discuss with the Science Research Council ways to take account of this possibility in allocating research grants—provided that use of the facilities is more or less guaranteed. It also suggests that establishments should continue to place research contracts in universities, especially for work likely to lead to military or commercial development.

Finally, it recommends that special relations between the establishments and neighbouring universities should be developed where appropriate and that location of neighbouring research establishments should be taken into account when starting new universities or colleges, and vice versa.

EXOTIC ACACIAS IN SOUTH AFRICA

A NUMBER of Australian phyllode-bearing acacias introduced into the Cape Peninsula of South Africa are now conspicuous members of the local vegetation. They include *Acacia melanoxylon*, *A. longifolia*, *A. cyclops* and *A. cyanophylla*. At first cultivated, they have for some decades been spreading by natural means, and the tendency of the different species to occupy particular habitats is evident. On the assumption that the salt content of soil could influence distribution, a greenhouse investigation has been made by Prof. E. A. Roux of the tolerance of these plants to sodium chloride[1].

Young plants were grown in water culture in washed river sand. A full nutrient solution of low osmotic pressure (0·5 atmospheres) was used as the basic medium, to which was added pure sodium chloride in varying amounts. Aeration was achieved by draining the containers daily. After the seedlings were established in the basic medium, they were subjected to increasing concentrations of sodium chloride until they died. The limits of tolerance were found to rise if the increases in salt concentration were made at longer as opposed to shorter intervals. Plants subjected directly to certain high concentrations were killed immediately.

With slow increases of concentration, *A. melanoxylon* would tolerate up to 2·4 per cent sodium chloride, *A. longifolia* up to 3·6 per cent and *A. cyclops* and *A. cyanophylla* up to 4·0 per cent. Other experiments indicated that *A. cyclops* was slightly less tolerant to salt than *A. cyanophylla*.

As a result of all the experiments, the species were finally placed in the following order of increasing salt tolerance: *A. melanoxylon*, *A. longifolia*, *A. cyclops*, *A. cyanophylla*. This sequence bears a direct relation to the altitudes at which the species normally grow on the Table Mountain range. *A. melanoxylon* grows above the 2,000-ft. contour. The upper limit indicated for *A. cyclops* is about 1,000 ft. and, for *A. cyanophylla*, slightly less. *A. longifolia* grows up to the 1,000-ft contour.

Prof. Roux plans soil tests so as to determine the average salt content of the soils in the different regions, but general physiographic considerations would point to an increase in salinity with decreasing altitude. The two species most highly tolerant of sodium chloride, *A. cyclops* and *A. cyanophylla*, are dominant on the Cape Flats where altitudes are generally less than 100 ft. above sea level. *A. cyclops* is the dominant and often the only species on dunes near the sea, and it was interesting to discover that it is rather less tolerant of salt than *A. cyanophylla* which tends to dominate on the more consolidated and level areas. It seems probable that drainage is more efficient on the dunes and that the consolidated and less-well-drained soils have a higher salt content.

AN INVESTIGATION OF MICROPULSATIONS AT MIDDLE LATITUDES

By M. J. USHER and W. F. STUART*

Department of Geophysics, Imperial College of Science and Technology, University of London

RUBIDIUM magnetometers were set up at the three United Kingdom observatories (Lerwick, geomagnetic latitude 62·5° N., Eskdalemuir 58·4° N., Hartland 54·6° N.) and simultaneous recordings of micropulsations occurring in the total field were obtained for the second half of 1964. The three stations are close to the same geomagnetic longitude and are about equally spaced at intervals of 400 miles.

The rubidium magnetometer is an atomic oscillator producing a frequency proportional to the scalar value of the ambient magnetic field. Details of its method of operation have been given earlier[1,2]. The magnetometer frequency of about 200 kc/s in the total Earth's field was counted by a commercial 1-Mc/s unit and decoded into an analogue step record. The sensitivity was 1/20γ with a sampling rate of about 1 per sec, which ensured that the frequency response of the system was flat from very long periods to 5 sec: a chart speed of 0·25 in. per

* Present address: Department of Meteorology, University of Edinburgh.

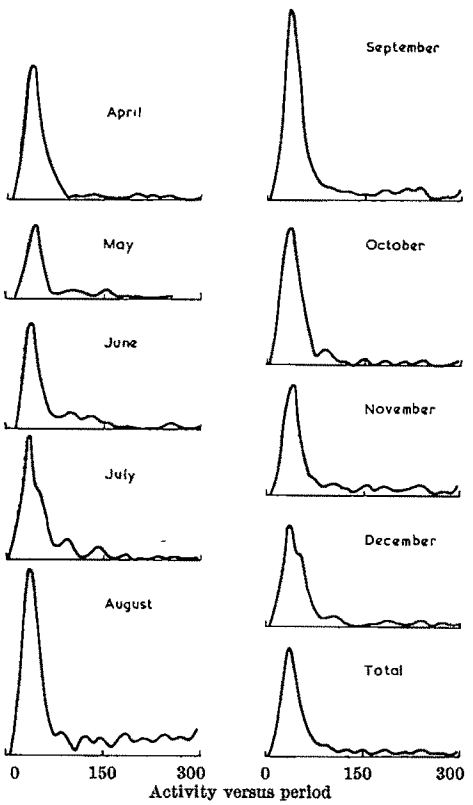
min was used. The instrumentation was operated by the staffs of the observatories.

Records were obtained from the three stations together for the period August 15–December 20, and from Hartland from April 25–December 31. They were analysed in the first instance by a hand-scaling technique, as the quantity of data obtained and the general nature of micropulsation activity made other approaches unrealistic. The characteristic periods of events occurring in hourly intervals were noted together with the average amplitude and a 'continuity' figure giving the number of 5-min intervals in 1 h for which a particular period was present. A 'continuity index' figure having a value 0, 1 or 2 was adopted as a general measure of degree of *Pc* activity. Events were designated *Pc* or *Pt* and good events were specially noted. Values of total field energy, proportional to the product of continuity and the square of the amplitude, were computed. The significance of energy is somewhat doubtful as it does not include components in the plane perpendicular to the field direction. A large number of tracings of good or interesting events occurring simultaneously or otherwise at the three stations were taken.

Occurrence diagrams were constructed from the data by representing any event by a dot on a plot of period versus time of day, producing a variable-density sonogram effect. The period intervals were in seconds from zero to two hundred and the time intervals in hours. Graphs of occurrence versus time of day for selected period ranges and of occurrence versus period for selected hourly intervals were then obtained by summing the dots in the required areas of the occurrence diagram. This was done for each station at intervals of 4 weeks.

This method of analysis is such that errors in measurements are adequately distributed. It is important to realize that the method of analysis and the results described here are of a very general nature. This procedure was thought to be advisable before a more detailed investigation was attempted.

Figs. 1, 2 and 3 are typical of the results obtained. Fig. 1 shows the seasonal variation of the *Pc* spectrum



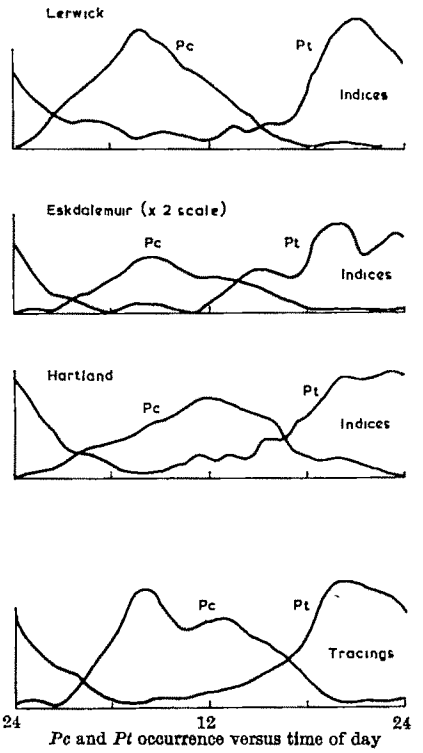


Fig. 1. Seasonal variation of the *Pc* spectrum at Hartland for the hours 07.00–12.00

Pc and *Pt* occurrence versus time of day

Fig. 2

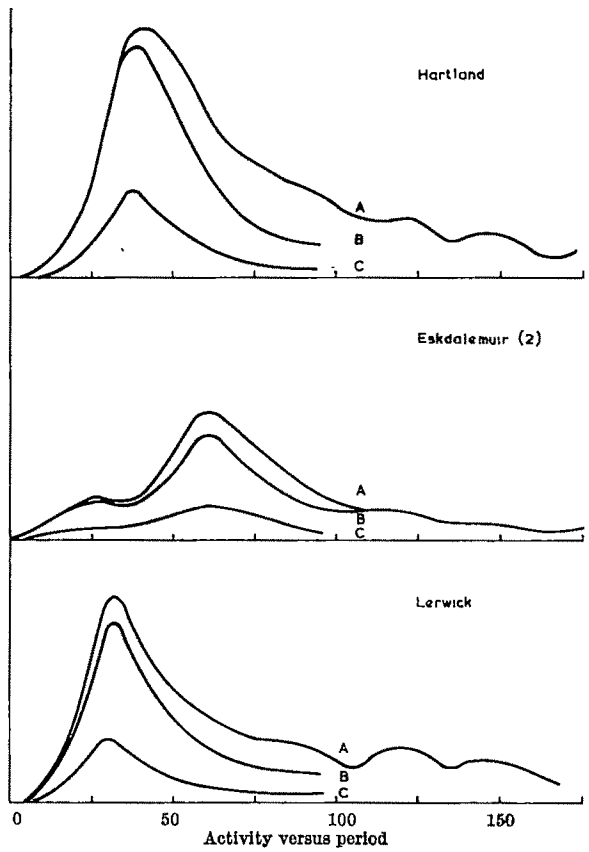

Fig. 3. *A*, Total; *B*, 03.00–17.00; *C*, best *Pc* hours

at Hartland (for the hours 07.00–12.00). A minimum in May/June and a maximum at the autumnal equinox are apparent. A suggestion of a decrease in peak period at times of increased activity is evident.

Fig. 2 is a plot of *Pc* and *Pt* occurrences at each station taken from the data sheet notations. A striking difference

between the times of maximum *Pc* occurrence at Hartland and Lerwick is evident, being 08.00 at Lerwick and 12.00 at Hartland. The *Pt* curve is similar at each station.

Fig. 3 shows period spectra for the three stations for periods up to 200 sec over the whole 24 h. The three stations contrast sharply, the peaks being 30 sec at Lerwick, 40 sec at Hartland and 60 sec at Eskdalemuir, where a subsidary peak occurs at 25 sec. This behaviour is not in agreement with the increase of period with latitude suggested by most theories.

Several distinct features arise from this general analysis of micropulsation activity:

(1) *Pc* occurrence times are radically different at the three stations, the maxima being 08.00 at Lerwick and 12.00 at Hartland. Related to the rotation of the Earth in a steady stream of solar wind, this represents 60° and is clearly an important feature in any theory of the origin of micropulsations.

(2) The general shape of the *Pc* spectrum is distinctly different at the three stations. The maxima are 30 sec at Lerwick, 60 sec at Eskdalemuir and 40 sec at Hartland, with a secondary peak of 25 sec at Eskdalemuir. This is not in agreement with theory but can be rationalized if harmonics are assumed to occur at the different stations. Harmonic activity is clearly evident on the records and apparently exists to a greater degree at the most northerly station. The period versus latitude variation shown by these curves does not agree with that found by Siebert[3] for stations at the same latitude in Germany.

(3) There is a seasonal change in both *Pc* and *Pt* activity. Hartland shows a maximum for *Pc* and *Pt* at the autumnal equinox, but Lerwick has a maximum in July/August for *Pc* and September/October for *Pt*. The statistical values are rather low, however, for *Pt* events.

(4) The peak *Pc* period decreases in times of increased activity, being shorter in the summer months. At such times *Pc* activity occurs earlier, especially for the shorter periods which then exhibit greater intensity. A similar diurnal variation occurs.

(5) Energy differences between stations are apparent, Eskdalemuir having only about half that at Lerwick and Hartland. This may be due to a crustal anomaly thought to exist in the region of Eskdalemuir, or could be due to the different proximity to the sea of the three stations. Measurements with a vector version of the magnetometer have shown that the total field record agrees closely with that obtained in the horizontal direction, since the vertical component is, in general, small.

This work is being extended to lower latitudes and an empirical investigation of the differences between Eskdalemuir, Lerwick and Hartland is being made with particular reference to inductive effects. A more detailed analysis of possible harmonic structure of good *Pc* events is being carried out using a vernier microscope, and *Pt* events are being measured for analysis by computer.

This work was supported by the Science Research Council and the British National Committee for Space Research. We thank the staffs of the various observatories for their attention to the instruments, and Miss Ann Clifford for compiling and presenting the analysis.

LOCAL GROUND-LEVEL AIR CONCENTRATIONS OF LEAD-210 AT WINCHESTER, MASSACHUSETTS

By B. SHLEIEN and DR. A. G. FRIEND
Northeastern Radiological Health Laboratory, Division of Radiological Health,
U.S. Public Health Service, Winchester, Massachusetts

LEAD-210 concentrations in ground-level air are of interest because it has been estimated by Holtzman[1] that about half the activity of this isotope present in human bones is acquired through inhalation. Lead-210 occurs naturally and, due to its long half-life (22 years), is not restricted to the vicinity of its origin. Burton and Stewart[2] estimated the mean atmospheric residence time for lead-210 to be approximately 4 weeks, a period sufficient to allow atmospheric transport and mixing to occur. Barreira[3] has found ocean air low in radon-222 and it has been assumed that this type of air mass would also have a low concentration of lead-210. Holtzman[4] attributed lower lead-210 values in the bones of island dwellers to the lower atmospheric concentration of lead-210 in ocean air. The purpose of the present investigation was to obtain information on lead-210 concentrations in ground-level air and to investigate the relationship between airborne lead-210 and air masses.

The sampling site located at Winchester, Massachusetts, is in a suburban area approximately 15 km from the Atlantic sea-coast north-west of Boston. Daily air particulate samples were collected on a 47-mm diameter membrane filter (0·8μ pore size). Tests of this filter media indicated it was highly efficient for collection of radon daughter aerosols. The collector was located approximately 2 m above the ground and sampled air at a rate of 28 l./min. Each sample represented approximately 30 m³ of air. The daily collections were composited on a monthly basis from July 1964 to June 1965.

The samples were stored for one month after collection to allow equilibrium between lead-210 and its daughter, bismuth-210. They were then solubilized and the lead-210 separated from fission products and bismuth-210 by an ion exchange technique developed by Hahn[5]. The method converted the lead and bismuth present to the chloride by addition of hydrochloric acid. Bismuth and lead carriers were added and the solution passed through an anion exchange resin in the chloride form. The bismuth and lead were absorbed from solution. The lead was eluted with dilute hydrochloric acid and the bismuth with sulphuric acid. The lead was further purified by precipitation as a sulphate and converted to the chromate for counting; the bismuth was precipitated as the oxychloride for counting.

After a 30-day delay (to allow the daughter product, bismuth-210, to grow into secular equilibrium with lead-210), the lead-210 activity was determined by β counting its daughter bismuth-210. Determination of bismuth-210 activity initially separated served as a check of the values obtained.

Wind speed and direction data were obtained with a recording anemometer and wind direction transmitter mounted on a 50-ft. tower. Temperature and rainfall were concurrently recorded on appropriate instruments at ground level. Daily United States Weather Bureau maps provided information on the type of air mass over the sampling site.

Monthly lead-210 concentrations in ground-level air are presented in Table 1. Monthly results are averaged together in cases where the individual results are within the counting error at the 95 per cent confidence level. These results are consistent with those reported by Patter-

son and Lockhart[6] for Washington, D.C. For purposes of comparison with meteorological data, the values of lead-210 and the respective meteorological parameters were averaged over the time periods indicated in Table 1.

Based on data obtained from U.S. Weather Bureau maps, the predominant air mass over the sampling site was continental polar air (cP). Continental arctic (cA) air, which originates farther north than does continental polar air, was present over Winchester, Massachusetts, during the winter months. Intrusions of maritime tropical air (mT) occurred for the most part during the summer months, while maritime polar air (mP) was infrequently present. Maritime air masses may be expected to have a lower lead-210 content than continental air masses because of their origin over ocean areas. The effect of maritime air was indicated by lower lead-210 air concentrations during July–August–September 1964, and March–April–May–June 1965, when maritime tropical and maritime polar air was present over the sampling site 29 and 21 per cent of the time, respectively. During November–December 1964, the period of maximum lead-210 concentration, these types of air masses were present only 5 per cent of the time.

Table 1. LEAD-210 CONCENTRATIONS IN GROUND-LEVEL AIR

Month	Lead-210 (pc./m³ ± E*) Monthly composite	Mean for period
July 1964	0·0140 ± 0·0011	0·0125 ± 0·0025
August	0·0100 ± 0·0011	
September	0·0135 ± 0·0021	
October 1964	0·0232 ± 0·0031	0·0232 ± 0·0031
November 1964	0·0328 ± 0·0041	0·0370 ± 0·0066
December	0·0412 ± 0·0052	
January 1965	0·0222 ± 0·0052	0·0231 ± 0·0061
February	0·0240 ± 0·0033	
March 1965	0·0150 ± 0·0037	0·0157 ± 0·0057
April	0·0162 ± 0·0023	
May	0·0172 ± 0·0026	
June	0·0149 ± 0·0026	

* Counting error at 95 per cent confidence level.

A relationship between local lead-210 air concentration and the prevalence of particular air masses is indicated in Fig. 1. The concentration of lead-210 varies negatively with the time that maritime tropical (mT), maritime polar (mP), and continental arctic (cA) × (0·3) were over the sampling area. This relationship has a linear correlation coefficient of 0·93. The 68 per cent (one standard deviation) confidence interval for this value is 0·74–0·98.

Fig. 1 indicates a line of best fit based on regression analysis. Extrapolating this linear relationship indicates that lead-210 would approach zero if the indicated air masses were present 40 per cent of the time. Such a lead-210 concentration is physically unlikely. The concentration of lead-210 in continental arctic air was assumed to be lower than that for continental polar air, because ice cover as well as smaller land surfaces in the area of its origin would tend to reduce concentration of this radionuclide. A correction factor of 0·3 for continental arctic air proved to fit best the linear relationship shown in Fig. 1.

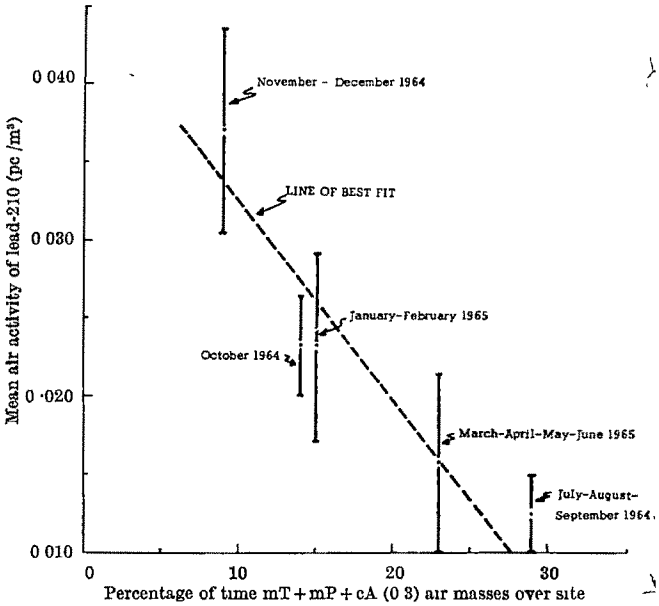

Fig. 1. Percentage of time that maritime tropical, maritime polar, and continental arctic × (0 3) air masses lay over sampling site versus the lead-210 concentration in ground-level air during selected sampling periods

Local meteorological parameters such as mean temperature, mean wind speed and direction, and precipitation, when averaged over the time periods indicated had a significant correlation with lead-210 except for easterly winds. A strong dilution effect by easterly winds, that is, winds carrying ocean air, was indicated by a correlation coefficient of 0·86 (0·53–0·97 for the 68 per cent confidence interval) for an inverse relationship between lead-210 concentrations and easterly winds. However, any relationships between local weather factors and lead-210 may have been lost in averaging the data over extended time periods.

The data on lead-210 in ground-level air collected at Winchester, Massachusetts, indicate that maritime air contains lower lead-210 concentrations than does continental air. It appears to support the hypothesis that lower values of lead-210 in the bones of island dwellers can be attributed to the lower atmospheric concentration of lead-210 over oceans.

CAESIUM-137 AND STRONTIUM-90 IN NORWEGIAN MILK, 1960–1964

By T. HVINDEN and A. LILLEGRAVEN
Division of Physics, Norwegian Defence Research Establishment, Kjeller

MEASUREMENTS of caesium-137 and strontium-90 in Norwegian milk since 1956 have revealed seasonal variations and variations from district to district[1–5].

Since 1960, milk has been sampled at the eleven places shown on the map in Fig. 1. At sites 1–10 the samples are collected from dairies which receive milk from farms spread over a relatively large area. At site 11, the samples are from a single farm. Samples are normally collected about twice a month.

Quarterly average concentrations of caesium-137 in milk for sites 1–10 from 1960 to 1964 are shown in Fig. 2,*A*. A marked seasonal variation is apparent with a maximum during the quarter July–September, that is, during the grazing season. This indicates higher uptake from slow-growing grazing fields than from the better-cultivated fields supplying winter fodder. The highest value in curve *A*, 640 pc./l., found in 1964, is about four times greater than in 1960 and 1961.

The results also vary from site to site, both in concentration level and in seasonal pattern. The concentrations at site 11 have been influenced by an unusual composition of the fodder at this site, containing, for

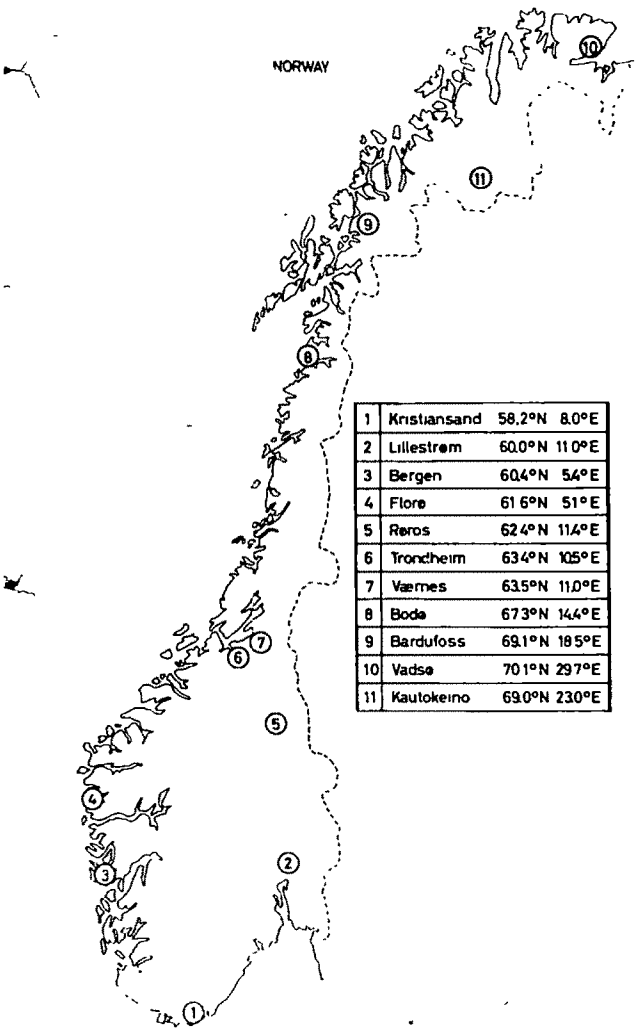

Fig. 1. Milk sampling sites

example, varying amounts of reindeer-lichen. This has sometimes given a maximum concentration during the first quarter.

The variations from district to district are evident in Fig. 3,*A*, which shows yearly average values of caesium-137 in milk at each of the eleven sites during the period 1960–64. The variations between sites follow the same general pattern from year to year, the highest concentrations being about eight times the lowest.

The variations do not follow the precipitation. As precipitation and caesium-137 deposition are to a first approximation proportional, the concentration in milk therefore depends on other factors in addition to deposition. These factors may be expected to involve feeding conditions, including quality of grazing fields and fodder composition, but there may be other less obvious influences. Based on the approximate proportionality between precipitation and caesium-137 deposition, the ratio of caesium-137 concentration in milk to yearly precipitation in the various districts gives an indication of the variations in these factors. Fig. 4,*A* shows average values of this ratio over the period 1960–64, in units of the ratio at site 2, with the sites arranged in order of increasing ratio. The highest value is about eleven times the lowest. The values are based on precipitation measurements made near the sample collection point. This represents an additional uncertainty, as each dairy receives milk from a large district within which there may be significant variations in yearly precipitation. The first four sites in Fig. 4 are inland, lowland districts, and show increasing ratios from south to north. The next five sites are coastal, largely mountainous districts, and also show increasing values from south to north. The last two sites are inland, mountainous districts, again showing increasing ratios

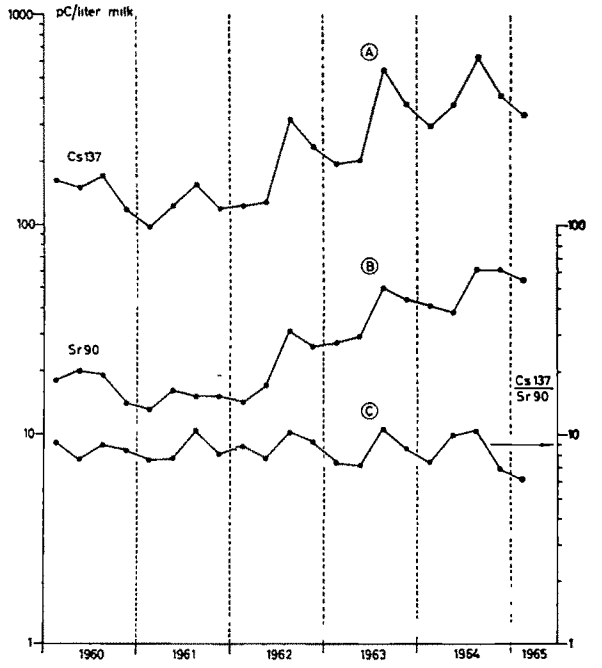

Fig. 2. Quarterly values of (*A*) the caesium-137 concentration, (*B*) the strontium-90 concentration, and (*C*) the caesium-137/strontium-90 ratio in milk, averaged over sites 1–10

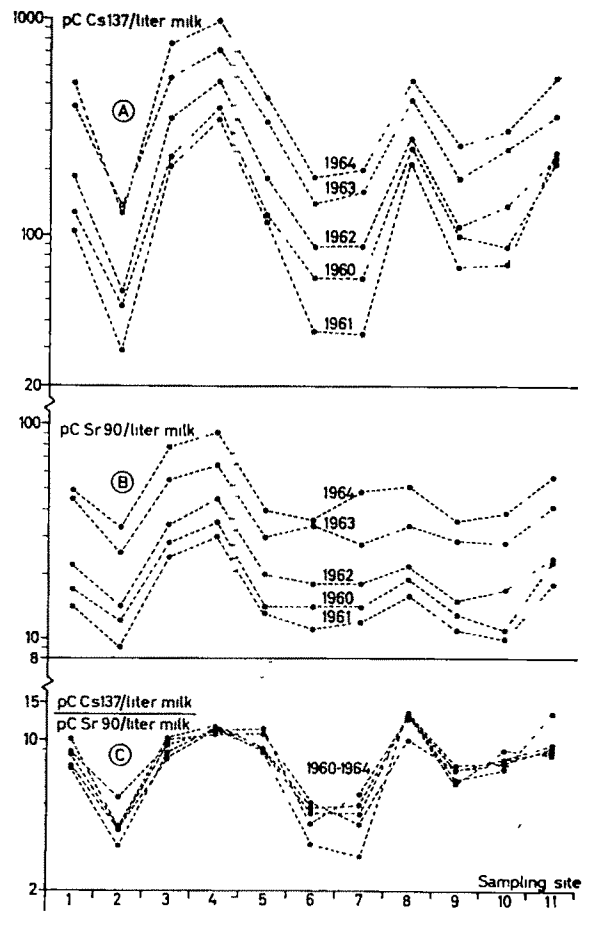

Fig. 3. Yearly average values at sites 1–11 of (*A*) the caesium-137 concentration, (*B*) the strontium-90 concentration, and (*C*) the caesium-137/strontium-90 ratio in milk

from south to north. These results indicate that inland, lowland districts have better feeding conditions than coastal districts, which in turn are better than inland, highland districts. This trend seems reasonable, as the growth conditions for vegetation in Norway normally deteriorate from lowland to highland and from south to north. Site 11 has the highest value, whereas it has the lowest precipitation. It is thus conceivable that the high uptake at this site reflects the local dry weather. However, results of other investigations carried out at this Establishment indicate that this is not necessarily the case. Sites with poor growth conditions, but with about ten times the precipitation at site 11, also have about ten times more caesium-137 in milk than site 11 (ref. 6). It was also shown that the uptake depends on the method of farming. At two neighbouring farms, one with modern, intensive farming, the other old-fashioned, the caesium-137 concentrations in milk at the latter were about ten times higher.

The dependence of caesium-137 milk concentrations on deposition can thus be expected to vary from district to district and from season to season as well as from year to year within the same district, depending on feeding conditions, which involve many factors of varying importance. A formula taking into account all factors, including delays or half-lives of the various stages, would be extremely complicated. For prediction purposes, a simplified model, even if less accurate, would still be very useful. Assuming that the caesium-137 concentration in milk, m, depends linearly on the rate of caesium-137 deposition, r, and on the cumulative deposition, c, a relationship can be written $m = a \cdot r + b \cdot c$. Owing to the difference between summer and winter feeding, the factors a and b have been determined separately for the two seasons. For the grazing season, that is, the quarter July–September, it has been assumed that the concentration, m, depends on the rate, r, during the same quarter and on the cumulative deposition, c, up to the middle of the quarter. For the winter-period the quarter January–March has been taken to be most representative, as during October–December the grazing season will be phasing out and during April–June it will be phasing in. For January–March it has been assumed that m depends on r and c for the quarter July–September of the previous year.

The rate and the cumulative deposition of caesium-137 for the various districts and years have been calculated from precipitation data and measurements of caesium-137 in soil samples and in air and precipitation since 1956.

The factors a and b determined for the average values over sites 1–10 are given in Table 1, together with the difference, in percentages, between the concentrations measured and those calculated using the expression $m = a \cdot r + b \cdot c$.

Table 1. RATE FACTOR a AND CUMULATIVE FACTOR b FOR UPTAKE OF CAESIUM-137 IN MILK

Periods	a	b	Max. deviations from measured values (%)
July-Sept. 1960–1964	14	3·3	11
Jan.-Mar. 1960–1965	6·5	2·5	26

Average values for sites 1 to 10.

$$a = \frac{\text{pc } ^{137}\text{Cs/l. milk}}{\text{mc. } ^{137}\text{Cs/km}^2\text{. 3 months}}$$

$$b = \frac{\text{pc. } ^{137}\text{Cs/l. milk}}{\text{mc. } ^{137}\text{Cs/km}^2}$$

The larger deviations for the first quarter are probably due more to the larger variations of fodder (hay, silage, turnips, lyed straw, processed cattle food, etc.) than to the inclusion of the first quarter of 1965.

The caesium-137 concentration in the diet will not always be directly related to the deposition in the district. For example, hay, straw and other fodder may be imported from other districts. The deviations will therefore be larger when the model is applied on the results from the separate sampling sites. The factors a and b for each of the sites 1–10 are shown in Fig. 4,*B*. The deviations from the measured concentrations in milk at any one site are, on average, 13 per cent for July–September and 22 per cent for January–March, with maximum values of 35 per cent and 46 per cent, respectively, for single quarters.

Because of the uncertainties involved in the model and the calculations, the curves in Fig. 4,*B* may be seen more as indicating the tendencies than as giving proportional relationships. The results indicate that the variations from district to district in caesium-137 concentration in milk relative to deposition are due more to variations in the cumulative factor than to change in the rate factor.

The concentrations of strontium-90 in milk during the years 1960–64 are shown in Fig. 2,*B* as quarterly average values over sites 1–10. The curve shows seasonal variations, but these are smaller than those for caesium-137. This difference between strontium and caesium is an indication of their different behaviour in the food chain.

The highest value in curve *B*, 60 pc./l. during 1964, is about four times greater than in 1961.

The variations from district to district, evident in Fig. 3,*B*, follow the same general pattern from year to year, the highest concentrations being about three times the lowest. The variations are thus smaller than for caesium-137. The ratios of strontium-90 concentration in milk to yearly precipitation are shown in Fig. 4,*A*. The highest ratio is about five times the lowest.

The districts, as for caesium-137, may be divided into three categories: inland lowlands, coastal mountains and inland highlands. Within each category, the ratio of strontium-90 to precipitation usually increases from south to north. But, in contrast to the caesium-137 ratio, not all ratios in the coastal districts are higher than in the inland, lowland districts. This shows that the strontium-90

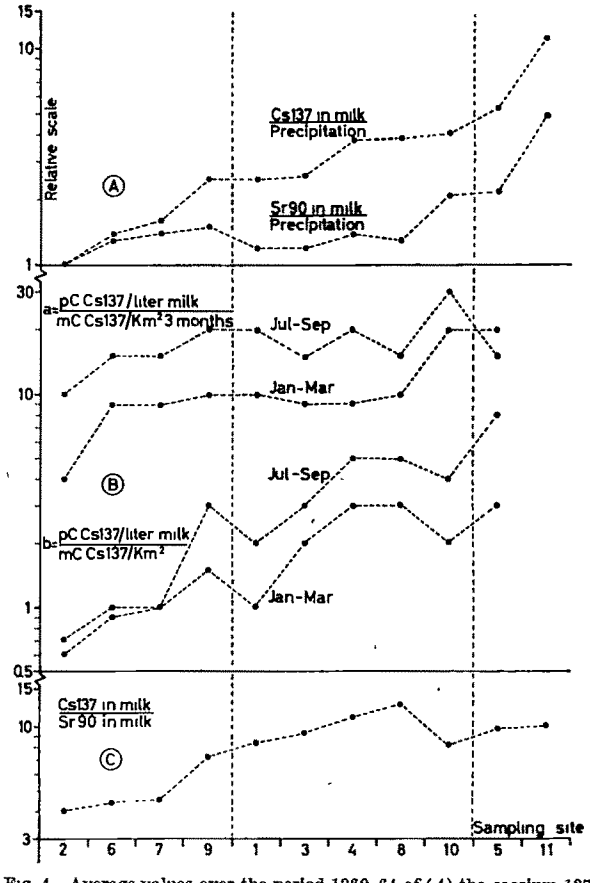

Fig. 4. Average values over the period 1960–64 of (*A*) the caesium-137 and strontium-90 in milk/yearly precipitation ratio, (*B*) the rate factor a and cumulative factor b for uptake of caesium-137 in milk, and (*C*) the caesium-137/strontium-90 ratio in milk at sites 1–11, arranged in order of increasing caesium-137 in milk/precipitation ratio

Table 2. RATE FACTOR a AND CUMULATIVE FACTOR b FOR UPTAKE OF STRONTIUM-90 IN MILK

Periods	a	b	Max deviations from measured values (%)
July–Sept. 1960–1964	2·1	0·56	14
Jan.–Mar. 1960–1965	1·5	0·53	17

Average values for sites 1 to 10.

$$a = \frac{\text{pc. } ^{90}\text{Sr/l. milk}}{\text{mc. } ^{90}\text{Sr/km}^2\text{. 3 months}}$$

$$b = \frac{\text{pc. } ^{90}\text{Sr/l. milk}}{\text{mc. } ^{90}\text{Sr/km}^2}$$

uptake in milk depends on other factors than the caesium-137 uptake, for example, the availability of calcium in soil.

The rate factor a and the cumulative factor b in the expression $m = a \cdot r + b \cdot c$ for uptake of strontium-90 in milk have been determined for the average values for sites 1–10, assuming the ratio of caesium-137 to strontium-90 deposition to be 1·7. The results are given in Table 2.

Values of the ratio of caesium-137 to strontium-90 in milk during the years 1960–64 are shown in Fig. 2,*C* as quarterly average values over sites 1–10. The ratio shows a seasonal variation with a maximum during July–September. This reflects the smaller seasonal variation of strontium-90.

There does not seem to be any systematic variation from year to year of these quarterly ratios. This may indicate that the ratio of rate uptake to cumulative uptake on the average has been about the same for caesium-137 and strontium-90. However, as is shown in Fig. 4,*B*, this may not be the case at the separate sites.

Fig. 3,*C* gives yearly average values of the ratio of caesium-137 to strontium-90 for each of the eleven sampling sites for the period 1960–64. It appears that the variations from district to district follow the same general pattern from year to year, the highest ratios being about three times the lowest, indicating that the differences are related to regional growth conditions rather than to other factors.

The average ratios over the period 1960–64 for each site are shown in Fig. 4. The lowest value is about 4, the highest about 13. The ratio increases from south to north, and is highest at the coastal sites, implying that the caesium-137 uptake in milk is more sensitive than the strontium-90 uptake to the growth conditions for vegetation.

Summarizing, the uptake of caesium-137 and strontium-90 in milk shows seasonal variations and variations from district to district. The variations seem to be more dependent on feeding conditions than on deposition. On the basis of the results for the period 1960–64 it seems feasible to make approximate predictions of milk activity from data on rate and cumulative deposition.

ELECTRON PARAMAGNETIC RESONANCE SPECTRA OF BONE AND ITS MAJOR COMPONENTS

By PROF ROBERT O. BECKER

State University of New York, Upstate Medical Center, and Veterans Administration Hospital, Syracuse, New York

AND

ANDREW A. MARINO

Veterans Administration Hospital, Syracuse, New York

A PRELIMINARY paper reported the detection of electron paramagnetic resonance (EPR) signals in non-irradiated human and amphibian bone[1]. Whole cortical bone was used in that investigation and the signals were described as multiple and anisotropic. The study was undertaken to obtain evidence to confirm the theory that some properties of bone result from a semiconducting *P-n* diode structure formed by the association between the mineral crystals and the collagen fibres of the matrix[2,3]. While the preliminary results neither confirmed nor refuted this thesis we wish now to report on a much more extensive study from which several interesting conclusions may be drawn.

While the literature is replete with reports of EPR studies on irradiated biological materials, we have found only scanty references to work on non-irradiated bone, collagen or mineral. Slager and Zucker[4] found no resonances in bone prepared for use in bone banks, and Cole and Silver[5] reported no resonances in a single deciduous tooth. Both these investigations were concerned primarily with the effects of irradiation and non-irradiated samples were employed only as controls. In discussing our preliminary communication, Commoner[6] stated that the resonance in whole bone was most likely due to the bone mineral, presumably apatite. Vinokurov and Zaripov[7] reported the presence of EPR signals in geological apatite. However, we have been unable to find any reports of similar studies on bone mineral. Likewise we have found no mention in the literature of EPR signals from non-irradiated collagen, derived either from bone or from soft tissue, except for the report by Abagyan[8] of complex signals from gelatine. Commoner and Ternberg[9,10], Swartz and Molenda[11] and Mallard and Kent[12] have all reported signals arising from whole, non-irradiated animal tissues of various types. However, none of these reports dealt with bone or with any type of collagen *per se*.

Bone samples. In the present investigation, powdered samples of human bone, collagen and mineral were used exclusively to avoid the complication which accompanied the previously reported anisotropic signals from whole bone. General sample procurement and treatment was as reported in detail in a previous publication, including the use of similar techniques for preparation of bone mineral and bone collagen. It is important to note that the extractions of collagen and mineral involve the use of aqueous solutions and subsequent washing in water. Once the basic samples were prepared they were stored in Petri dishes under normal laboratory conditions relative to temperature, humidity and illumination. In the present experiments these basic samples were reduced to powder by scraping with a sharp glass fragment (microscope slides were routinely used and discarded as soon as they showed signs of wear). The bone samples were held by hand in a paper tissue and no metallic objects were used in any part of the preparation procedure. This method resulted in a fine granular powder, uncontaminated by metallic or glass fragments, which was used for all samples except for the rat tail tendon. In this case the

fibres were obtained by stripping away from the bony structures; the portion of the tendon which had been grasped by the metallic clamp was then cut off and discarded. The fibres were permitted to equilibrate to room conditions, then sectioned into pieces of less than 1 mm length using sharp scissors. Dehydrated samples of all materials were prepared by vacuum drying at a pressure of 10μ of mercury for a minimum of 2 weeks. During the first few days of this period the vacuum chamber was repeatedly flushed with dry nitrogen. This procedure was primarily intended to produce the maximum water loss without producing heat denaturation of the protein components.

EPR techniques. Samples were examined in 4 mm optically dense quartz tubes; each tube was previously checked for resonances utilizing the same instrument settings to be subsequently applied to the sample. Tubes with any major resonances in the $g2$ vicinity were discarded. In order properly to compare signals of the two components with the whole bone signal, tubes were filled according to a 2 : 1 ratio of mineral to collagen. This resulted in the whole bone sample tubes containing 150 mg of material, the mineral tubes 100 mg and the collagen tubes 50 mg of material. A Varian '*X*-band' spectrometer with 100 k.c. field modulation and phase detection with a time constant of 0·3 sec was used. Variable temperature studies were done using a Varian variable temperature attachment utilizing a constant flow of dry nitrogen at the desired temperature; g values were calculated from a determination of the klystron frequency using a Hewlett–Packard wavemeter, type '*X*532*B*'. The first derivative of the absorption signal was recorded.

(*A*) *Whole bone powder*

Hydrated. At room temperature all samples showed a clearly defined single resonance at $g2{\cdot}001$ ($\pm 0{\cdot}005$) with a line-width of 10 ± 1 gauss. This resonance saturated at about 100 dB (Fig. 1). The total signal amplitude decreased very slowly with storage under dark conditions. In general a decline to 30 per cent of the original value was apparent after 90 days. The other signal parameters, however, remained unchanged.

Dehydrated. Vacuum drying resulted in approximately a four-fold increase in signal amplitude, but again the other parameters of the signal remained unchanged.

Resonance signal variations with temperature. The amplitude of both hydrated and dehydrated samples had the same temperature dependence in the interval −150° C–+20° C (Fig. 2). In this region the curve was found to be reproducible. On heating, however, hydrated bone showed a discrete shift to a smaller amplitude in the vicinity of +65° C (Fig. 3), while dehydrated bone showed a more gradual transition to smaller amplitudes over the range +20° C to +95° C. In both cases, the decrease is much greater than one would expect on the basis of a simple Curie dependence. The decrease in signal amplitude at +65° C appeared to be irreversible. Each sample demonstrated this phenomenon one time only and, provided a sample was not carried beyond +100° C (with resultant loss of volatile components), when returned to +20° C did not regain the original signal amplitude. Further heating to +200° C caused the hydrated sample signal to increase in magnitude while the dehydrated sample signal remained essentially constant. Heating of a hydrated sample in a +800° C flame for 3 min caused the signal to increase by a factor of 100. In all heating experiments including the burning in a +800° C flame, the g-value and line-width of the observed resonance remained constant.

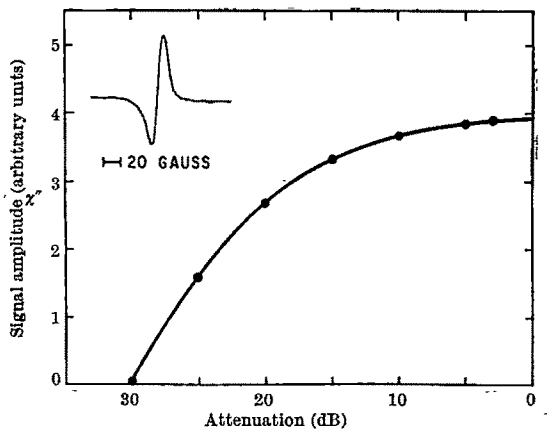

Fig. 1. Saturation of resonance from hydrated whole bone powder. The insert shows the standard resonance observed from this material

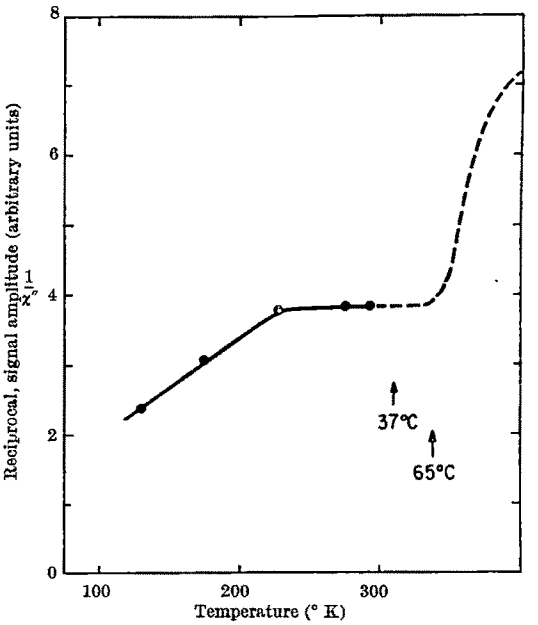

Fig. 2. Temperature dependence of reciprocal of signal amplitude from hydrated and dehydrated whole bone powder. The solid portion of the graph is stable and reproducible. The large sample temperature gradient (10° C) and temperature controller 'dead band' at present preclude assigning definite points to the curve above +300° K, that is, slope of dotted line depends on details of heating experiment. However, the abrupt signal change in vicinity of +65° C was routinely observed and is approximately as depicted

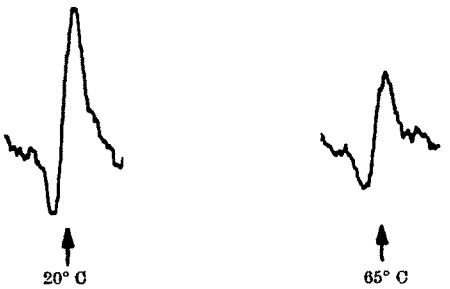

Fig. 3. Comparison of resonance signal amplitude from whole bone powder at room temperature and at +65° C. The shift to a lower amplitude appears to occur rather abruptly in the vicinity of +65° C

(*B*) *Bone mineral powder*

Hydrated. At room temperature a complex resonance (Fig. 4*A*) was observed, composed of several unresolved resonances with the largest slightly to the low field side of $g2$. In addition three equally spaced, low amplitude resonances have been found farther to the low field side. The low amplitude resonances are relatively independent of temperature, and disappear when the apatite is heated above +150° C. Storage in the dark for 90 days did not result in any appreciable decline in signal amplitude.

Dehydrated. At room temperature there was a slight increase in total resonance amplitude compared with hydrated apatite, but there was considerable improvement in resolution indicating the presence of three separate resonances in the $g2$ area (Fig. 4*B*). These are subsequently

identified as apatite resonances I, II and III with resonance III having a g-value very close to $g2$ and I and II being displaced towards the low field side of III. A careful inspection of the resonance observed in the hydrated sample reveals that the same three resonances are probably present in the one complex signal but with such low resolution as to be practically indistinguishable. The three low amplitude, low field resonances are still present but reduced in amplitude.

Resonance signal variations with temperature. (Fig. 5.) Both hydrated and dehydrated samples displayed the same series of changes with temperature. On cooling from room temperature to $-50°$ C there was a slight increase in total signal amplitude showing roughly an inverse dependence on temperature. In the vicinity of $-100°$ C a decrease in signal amplitude occurs and continues until at $-154°$ C the total signal amplitude is approximately 50 per cent of that at room temperature. These changes between room temperature and $-154°$ C are completely reversible. Heating the samples from room temperature to $+150°$ C results in a monotonic decrease in amplitude of the total resonance. At $+150°$ C, resonance I is no longer observable or combined with resonance II. The amplitude of resonance II is reduced sufficiently to render resonance III quite prominent. Between $+150°$ C and $+250°$ C there is a further reduction in the resonance representing the combination of I and II while resonance III demonstrates a real increase in amplitude. This same process (decrease in amplitude resonances I and II, increase in resonance III) continues up to $+300°$ C. If the heating process is halted at this point, and the sample cooled to room temperature and examined, a signal much different than the previous room temperature signal is seen.

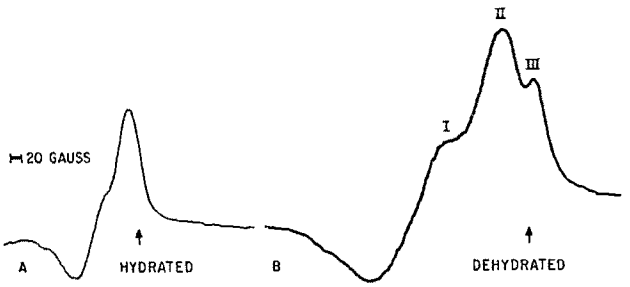

Fig. 4. Resonance signals obtained at room temperature from extracted bone mineral, hydrated (A) and dehydrated (B). The three low amplitude resonances towards the low field side of $g2$ are not pictured. There appear to be three resonances in the vicinity of $g2$; the numbers assigned to them on the dehydrated resonance (B) correspond to the numbers in the text. The scale of the horizontal axis of B is twice that of A

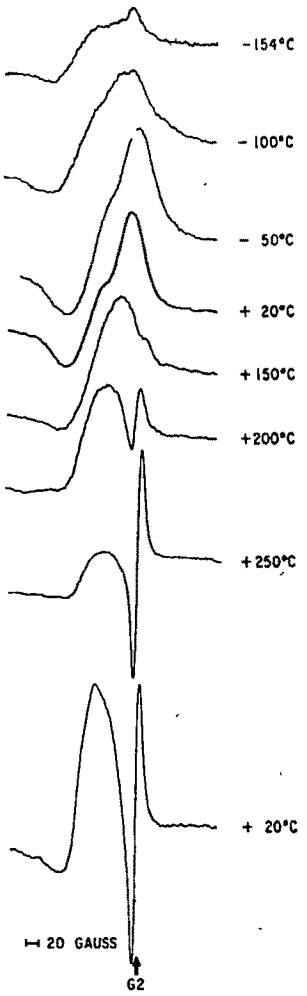

Fig. 5. Variations in the resonance signals from bone mineral (dehydrated in vacuum) with temperature changes. Instrument gain was reduced 50 per cent for the $+250°$ C temperature recording

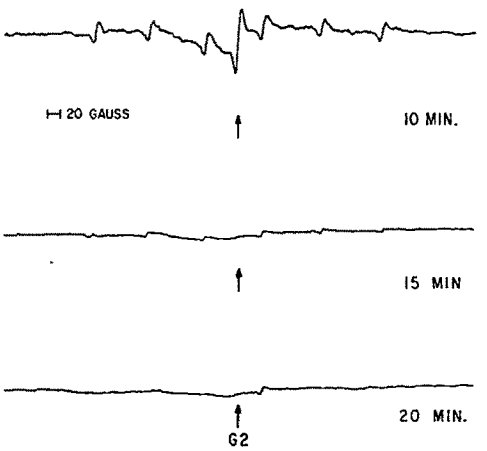

Fig. 6. Alterations in the resonance from bone mineral with exposure to $+800°$ C temperature for varying periods of time

Detailed experiments on bone mineral in the temperature range $+300°$ C to $+800°$ C using a muffle furnace are in process. However, the following preliminary observations have been made (Fig. 6).

(1) By heating to constant weight at $+400°$ C the broad low field resonance may be eliminated leaving essentially resonance III with a line-width of 10 gauss; g-value determinations were within the same range as the $g2$ signal from whole bone.

(2) By equilibrating mineral showing only a $g2$ resonance in distilled water for 24 h, the low field resonance may be partially restored.

(3) Transient heating in a $+800°$ C flame causes a decrease in the $g2$ resonance and the appearance of six satellite lines.

(4) Further flame heating causes the complete disappearance of the $g2$ line and a diminution of the satellite lines.

(5) Heating to constant weight at $+800°$ C causes the satellite lines to disappear completely with the exception of the first on the high field side.

The 'resolving' of the $g2$ resonance in apatite by heating to $+400°$ C enabled studies of its temperature dependence in the range $-154°$ C to $+200°$ C to be made (Fig. 7).

(C) *Collagen*

All samples of collagen, whether from rat tail tendon or human bone, that were immersed in water as a routine part of the preparation procedure displayed approximately the same complex signal: a broad peak towards the low field side of $g2$, a slightly narrower asymmetric peak closer to $g2$ and a partially resolved peak at $g2$. These resonances are hereafter referred to respectively

as I, II and III (Fig. 8*A*). Samples dehydrated in vacuum were essentially the same except for a slight increase in amplitude and resolution of the *g*2 peak (Fig. 8*B*). The only samples of collagen not immersed in water during preparation were those from rat tail tendon. These were found to have only the *g*2 peak (Fig. 8*C*). If these samples were immersed in water and air dried they displayed a resonance identical to hydrated bone collagen (Fig. 8*D*). Subsequent vacuum drying produced a resonance similar to that of vacuum dried bone collagen. Bone collagen stored under dark conditions for 90 days demonstrated approximately a 30 per cent loss in signal amplitude.

Signal variation with temperature

Bone collagen. Over the temperature range −154°–+150° C, resonance I appeared to increase slightly. Resonance II displayed a slight increase below −50° C, remained constant in amplitude between −50° C and +65° C, and decreased between +65° C and +150° C. Resonance III exhibited a constant decline from −154° C to +150° C. Since this resonance is poorly resolved, we cannot be certain whether it follows a strictly Curie dependence.

The signal complex composed of peaks II and III displayed a rather abrupt decrease in signal amplitude in the vicinity of +65° C. This phenomenon is somewhat easier to observe in the dehydrated bone collagen samples than in the hydrated. When samples that had been carried to +150° C were returned to room temperature, signals I and III were found to be relatively unchanged while signal II remained diminished in amplitude.

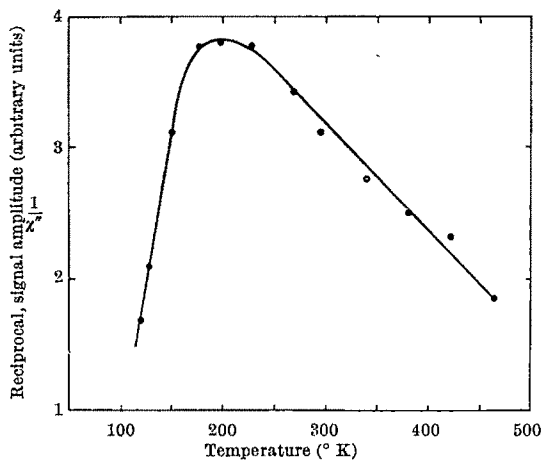

Fig. 7 Temperature dependence of reciprocal of signal amplitude from bone mineral treated to show only the *g*2 signal (heated to +400° C)

Rat tail tendon. The *g*2 signal was relatively independent of temperature between −154° C and +65° C. At the latter temperature an abrupt shift to a smaller amplitude is observed. Heating over +100° C produces an increase in signal amplitude that may well be ascribed to the loss of volatile materials.

In general, on an equal weight basis the signal amplitude from human bone collagen is approximately three times as great as that from rat tail tendon

Bone mineral. The resonance signals obtained from bone mineral appear to have considerable significance both in lending support to the thesis that the material is hydroxyapatite and in substantiating some concepts of its structure.

In order to explain the low calcium–phosphorus ratio in many hydroxyapatites it has been postulated that $2H_3O^{++}$ may be substituted for Ca^{++} in the crystal lattice, up to a maximum of four hydronium ions per unit cell. One of the chief successes of this theory is in explaining the observed water loss of apatite as a function of temperature. Experimentally, it is found, when heating apatite to constant weight, that weight is lost in a series of three

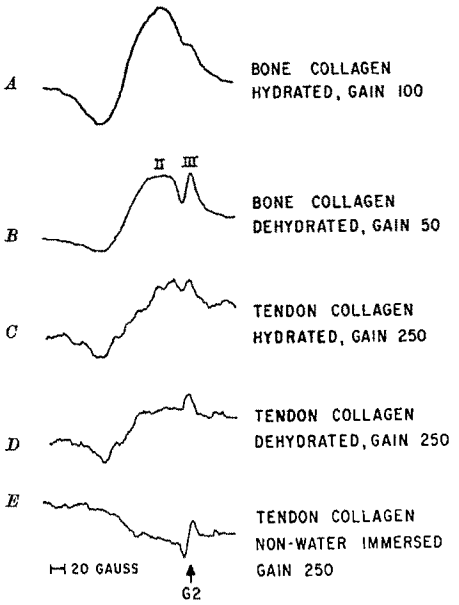

Fig. 8. Resonance signals from various types of collagen at room temperature The numbers on resonance *B* (dehydrated bone collagen) correspond to those in the text. Resonance I, the broad low field signal, is not pictured in the figure

discrete steps terminating at temperatures of +110° C, +400° C and +600° C (ref. 13). These changes have been attributed to an initial loss of surface absorbed water, a loss of substituted hydronium ions and, thirdly, to liberation of hydroxyl radicals from the unit cell.

A strikingly similar series of changes takes place in the EPR signal with temperature. Heating to +150° C eliminates the three low amplitude resonances and diminishes resonance II. Heating to +400° C almost completely eliminates I and II, leaving only the *g*2 resonance (III), and heating from +400° C to +800° C reveals the complex series of changes previously described. Prolonged heating at +800° C eliminates all resonances except the first high field satellite line.

Substituted hydronium ions (or similar type units) can produce a resonance signal. If it is postulated that the 'surface absorbed' water is somewhat similarly structured and capable of producing a resonance, then a high degree of correlation may be noted between the weight changes with temperature and the EPR signal changes with temperature, resonance II arising from surface-absorbed water and resonance I from H_3O^{++}. Further evidence for attributing the resonances in apatite, with the exception of the *g*2 resonance, to some form of water is provided by the work of Siegel *et al.*[14] on γ-irradiated ice. Among the resonances they found is one that is strikingly similar to the one we have found, showing resonance I (including the low field resonances) and resonance II, and differing only in that the unresolved resonance at *g*2 appears to be missing. While Siegel attributes the resonance to water the possibility remains that it is due to H_3O^{++} (or, alternatively, that water and not H_3O^{++} is substituted in the crystal lattice). In addition it should be noted that the broad low field resonance I may be enhanced by immersing the apatite in water for 24 h.

Vinokurov[7], investigating the EPR signal of blue geological apatites, finds in addition to Mn^{++} lines a relatively intense line at *g*2 of width 10 gauss, with six satellite lines symmetrically displaced of lesser intensity. He finds that the lines disappear at about +500° C, and attributes them to *F*-centre electrons localized at halogen ion vacancies (the position normally occupied by hydroxide in hydroxyapatite). As previously described, the same spectra with the notable absence of Mn^{++} lines are found in bone apatite in transient heating, and could presumably be produced by heating to constant weight in

the temperature range +400° C to +800° C. Significantly, the temperature at which the seven line spectra in bone apatite disappear, +800° C, is also the temperature at which the hydroxyl ion is driven off, collapsing the unit cell, and converting bone apatite into tricalcium phosphate. Commercially purchased tricalcium phosphate is found to have no resonance Thus, the $g2$ resonance in apatite is tentatively identified as being directly associated with either the hydroxyl radical itself, or electrons localized in hydroxyl vacancies (F-centres).

It is difficult to explain the observed anomalous temperature dependence of the $g2$ signal (Fig. 7) on the basis of strictly localized electrons as postulated by Vinokurov[7]. If one assumes that the trapped electrons do not participate in the resonance an alternative model that does fit the observations would be an excess of conduction electrons in equilibrium with the traps at +200° K (the observed signal minima), all traps would be considered filled, the resonance arising from the excess free electron population. Heating above +200° K would release increased numbers of electrons from the traps, thereby augmenting the resonance. Cooling below +200° K also leads to augmentation of the signal, derived in this case from the population of excess free electrons by virtue of the classical Curie dependence. On the basis of this picture, one may expect that there exists a temperature range in which all the traps are emptied, yet which lies below the temperature at which the onset of conversion to tricalcium phosphate begins (+600° C). In such a range, the resonance amplitude would be independent of temperature, except for the Curie dependence.

From a consideration of the data we conclude that resonance II (and the three low field resonances) results from surface-absorbed water possessing a structure capable of producing a resonant signal. Resonance I is tentatively identified with either H_3O^{++} ions or water in substitution positions within the lattice. The $g2$ resonance would appear to be derived from hydroxyl radicals, F-centre electrons, or conduction electrons. The similarity of the high temperature spectra sequence to that observed in geological apatite is striking but obviously not conclusive.

Collagen. All samples of tendon collagen initially demonstrated only the $g2$ resonance and within the confines of the experimental procedures did not indicate the presence of paramagnetic ions either as functional constituents or as impurities. Following exposure to aqueous solutions and subsequent drying (in air or vacuum) the resonance became practically identical with that of bone collagen, except in magnitude.

The resonance produced in rat tail collagen by water immersion (II) could be removed by heating to +150° C, while with bone collagen it was only partially removed. The line shape intensity and position of the remaining resonance (II), in +150° C heated bone collagen, together with spectroscopic data[15], strongly indicate that it is a result of residual apatite. Since the preparation of bone collagen involves prolonged exposure to aqueous solutions it must be considered possible that its unaltered, *in vivo*, resonance is also a similar single $g2$ peak. The data indicate that the broad resonance, II, observed after such exposure results from water structured on or within the collagen fibres which is structured in such a fashion as to be capable of producing an electron resonance. Since the water is apparently quite tightly bound to the collagen structure one may well question the relationship between structural or electronic data determined on collagen prepared in such a fashion with native unaltered collagen *in vivo*. In addition the data lead to the conclusion that both bone collagen and rat tail tendon collagen are not in free equilibrium with the water of the extracellular fluid. This is scarcely surprising for the type of bone collagen utilized (which is probably representative of 'unexchangeable bone'), but it is quite unexpected in the case of the tendon collagen.

The abrupt decline in signal magnitude in the vicinity of +65° C is indicative of a corresponding alteration in electronic structure. This phenomenon may, however, not be as abrupt as it would appear to be at first glance. For example, the curve of signal variation against temperature for bone (Fig. 2) shows a similar abrupt change at +65° C, but this transition terminates a temperature sequence from −50° C to +65° C within which the signal amplitude does not change with temperature. Below −50° C the signal follows a Curie dependence quite exactly. One has, therefore, rather than an abrupt anomaly occurring at a single temperature, an anomaly spread over a rather wide temperature range which is terminated abruptly at +65° C. It is interesting to reflect on the fact that the collagen *in vivo* exists in this anomalous state and that the temperature at which the state is terminated coincides quite well with the temperature at which the well-known 'shrinkage' phenomenon occurs.

Bone. The previously reported resonance signal at $g2$ is confirmed by the present investigation. The signal described in the present article is much greater in amplitude and much better defined than that previously reported because the total mass of specimen present in the powdered form is many times greater than the mass of the intact specimens used in the previous experiments.

The temperature dependence of the signal amplitude parallels that of collagen so well that the signal must be considered to derive, at least in part, from collagen. It is certainly not due solely to the presence of the apatite. While we cannot state with certainty the state of hydration of the apatite present in whole bone, all available evidence[13] indicates that at least that portion of the hydration represented by the substituted hydronium ions is present. One might therefore expect to see at least some of apatite resonance I in addition to the $g2$ resonance. However, none is found. In consideration of these facts it is surprising that the whole bone signal observed was consistently a relatively narrow, symmetrical intense line at $g2$. In general, the results are in accord with the thesis that the apatite–collagen relationship in bone produces a new unit with properties that are more than the simple additive sum of the properties of both components. If one may somewhat arbitrarily compare the single $g2$ signal of whole bone, with the corresponding signal of rat tail tendon collagen and that of apatite which has been heated to +400° C, few differences can be seen on superficial examination. However, the saturation curve for whole bone (Fig. 1) shows the onset of saturation at 10 dB, while a similar curve for both collagen and apatite reveals saturation in the vicinity of 15 dB, indicating some basic dissimilarity. In addition, the temperature dependences of bone powder and heated apatite are quite different.

To sum up, EPR observations have been made on powdered samples of whole human bone, bone collagen, bone mineral and rat tail tendon collagen.

(1) All substances examined revealed resonance signals.

(2) The resonance signal from bone mineral is quite similar to that derived from geological apatite within a certain temperature range and is attributed to certain types of structured water as well as F-centre electrons localized at the hydroxyl ion position and possibly conduction electrons.

(3) There is a distinct difference between the signals exhibited by water immersed and non-water immersed collagen. This is at present attributed to the ability of the collagen fibre to 'structure' absorbed water to a high degree.

(4) Collagen and bone exhibited an anomaly in the curve of signal against temperature at +65° C. The possible relationship between this and the shrinkage phenomenon is indicated.

(5) No paramagnetic species were found in any of the materials, either as functional components or as contaminants.

(6) The resonance signal in bone is not attributable to either apatite or collagen alone or to a simply additive sum of the resonances of both of these substances in combination.

This investigation was supported by a grant from the National Institutes of Health, U.S. Public Health Service.

ELECTRON SPIN RESONANCE IN SURVIVING RAT TISSUES

By DR J. R. MALLARD* and M. KENT*
Department of Physics and Biophysics, St. Thomas's Hospital Medical School, London, S.E.1

IN a previous communication[1] we presented some preliminary electron spin resonance results on normal tissues and tumour tissues from rats, confirming the earlier results of Commoner and Ternberg[2]. We have now made a more thorough investigation of these and other tissues with the addition of a continuous averaging technique system to our spectrometer[3]. A number of measurements have been made to determine more accurately the concentration of spins, the g-value and the line width observed from normal rat tissues. Samples of liver, kidney, heart, spleen, lung muscle and whole blood were investigated. In addition, several rat tumours were also studied. The results for the normal tissues are shown in Table 1 and those for the tumours in Table 2.

Table 1. CONCENTRATIONS OF FREE RADICALS IN VARIOUS TISSUES, g-VALUES AND LINE WIDTHS MEASURED BETWEEN THE POINTS OF INFLEXION OF THE ABSORPTION LINES

Also shown are the standard errors of the mean for each result, which, in the case of spin concentration, includes the calibration error

Tissue	Concentration of spins (moles/g) 10^{-9}	g-Value	Line width between points of inflexion (G)
Liver	8·58 ± 0·62	2·004 ± 0 0003	13·6 ± 0 2
Kidney	5·63 ± 0·33	2·004 ± 0·0002	13·7 ± 0·4
Heart	4 74 ± 0·42	2 003 ± 0·0002	14 0 ± 0·9
Spleen	0·99 ± 0 12	2·002 ± 0·0005	13·3 ± 0 5
Lung	0·79 ± 0·09	2·001 ± 0·0005	14 4 ± 0 5
Muscle	1·26 ± 0·40	2·002 ± 0·001	13 8 ± 1 4
Blood	0·1	—	—

Table 2. CONCENTRATION FOUND IN VARIOUS RAT TUMOURS OF FREE RADICALS AND OTHER PARAMAGNETIC SYSTEMS, g-VALUES AND LINE WIDTHS BETWEEN THE POINTS OF INFLEXION OF THE ABSORPTION LINE (TURNING POINTS ON FIRST DERIVATIVE SPECTRA)

Tumour type	Concentration of spins (moles/g)	g-Value	Line width between points of inflexion
Metastases of liver tumour	$(4·7 \pm 0 6) \times 10^{-6}$	2·011 ± 0 005	51·8 ± 0·8
Liver carcinoma	$(2·4 \pm 0·7) \times 10^{-6}$	2·016 ± 0·005	50·5 ± 2 6
Kidney carcinoma	$1·7 \times 10^{-9}$	2·002 ± 0·002	14 1
Radiation induced tumour	$2 4 \times 10^{-10}$?	2·004 ± 0 002 ?	10 ?
Sarcoma from congenital spina bifida	$3 2 \times 10^{-10}$?	2·004 ± 0 002 ?	11 ?
Eye tumour	$< 10^{-10}$	—	—
Breast tumour	$< 10^{-10}$	—	—

Measurements without standard errors indicate that only one sample was used. The maximum uncertainty here must be the concentration of impurity signal noted in the measuring system, which is of the order of 2×10^{-10} moles/g or giving a signal equivalent to that concentration. As a result, samples with signals of this order are in doubt as indicated.

The measurements on normal tissues were made on three samples of 100 mg of tissue from each of six rats in 5 per cent glucose solution; they show a surprisingly small standard error between samples. The results are shown diagrammatically, including the various standard errors, in Fig. 1. In this, the thick horizontal line represents the standard error of the mean of the sample measurements only on the inside edge, the outside edge being with the addition of the errors due to the calibrating standard sample used, which was an aqueous solution of 10^{-5} moles/l. manganese chloride. The narrow horizontal lines of wider spacing are the standard deviations of the tissue samples from the mean.

All measurements were made at 37° C cavity temperature and were averaged over 100 sweeps each of 8-sec duration. As was reported[1,2], the signals decay with time so that these figures must eventually be corrected for the decay occurring in that time. They will thus be slightly higher than reported here.

The results differ from those of Commoner and Ternberg[2] by a factor of approximately two. This may arise solely in the comparison of the experimental samples, which we assume have a spin of 1/2, with that of the calibrating standard, Mn^{++}, which has a spin of 5/2; the relative areas beneath the total absorption line shapes of samples of each of these spins with equal molar concentration we take to be not 5 : 1 but 35 : 3, due to the unequal population distribution in each of the six spin states of the Mn^{++}.

The following observations about the results from each tissue should be pointed out. Background spectra were subtracted as described previously[3], by recording the result of 100–300 sweeps, with glucose alone in the sample cell, on magnetic tape in digital form. In order to preserve, as far as possible, the advantages of the continuous averaging technique system with regard to improvement in signal-to-noise ratio, the background spectra were taken over a greater number of sweeps than that of the sample. They were then multiplied by a suitable constant when subtracted.

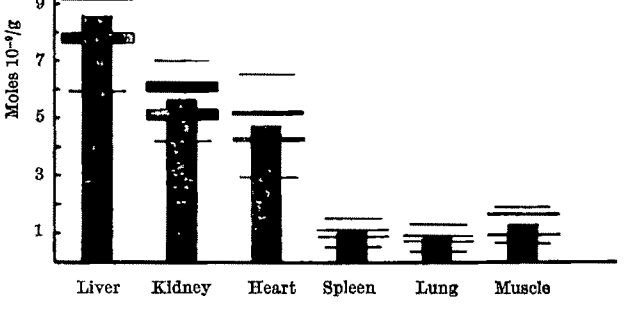

Fig. 1. Concentration of free radicals in a number of rat tissues measured at 37° C

* Present address: Department of Medical Physics, University of Aberdeen.

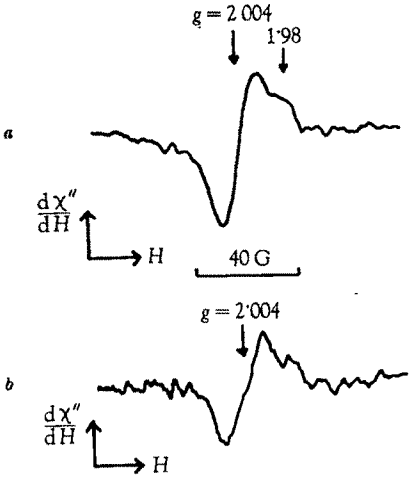

Fig. 2. (*a*) Fifty sweeps of rat liver after background spectrum subtraction. Modulation amplitude ~10 G; analyser display 10^5 counts full scale. (*b*) Twenty sweeps of the same sample with low modulation (~3 G). Analyser display 2×10^4 counts full scale

(*a*) *Liver.* For normal rat liver, the integration technique was a manual one. This explains the larger standard error for these particular results. In addition to the free-radical line, other less intense lines were observed around $g \sim 1{\cdot}98$ and 2·01 (Fig. 2), when the modulation amplitude was reduced to about 3 G. These lines were not accounted for in the integration, the results here being for a single free radical line only. A definite asymmetry was also observed and this will be discussed later.

(*b*) *Kidney.* The integration procedure, again for the free radical line observed at $g = 2{\cdot}004$, was semi-digital, the first derivative signal being integrated once only with the continuous averaging technique and the absorption line being plotted on homogeneous paper and weighed. The general appearance of the signal was similar to the liver, bearing the asymmetry observed before but to a lesser degree (Fig. 3).

(*c*) *Heart.* The integrations in this case were carried out in a completely digital manner using the continuous

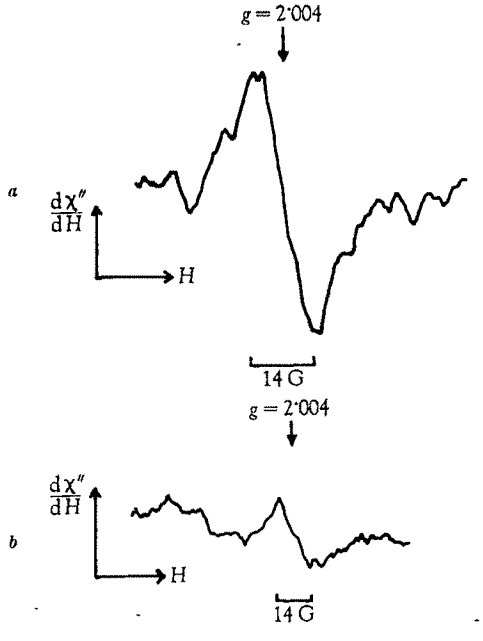

Fig. 3 (*a*) 100 sweeps of normal rat kidney. Signal represents $\sim 5 \times 10^{-9}$ moles/g on the analyser display scale of 10^5 counts full scale. The magnitude of the field sweep was ~90 G. (*b*) 300 sweeps of spontaneous rat kidney carcinoma. Signal represents $\sim 2 \times 10^{-9}$ moles/g on the analyser display scale of 5×10^5 counts full scale. The field sweep was ~130 G

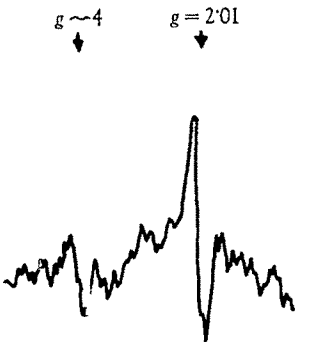

Fig. 4. Single sweep over 3·000 G of metastasis of liver tumour showing presence of signals at $g \sim 4$ and $g = 2{\cdot}01$

averaging technique. There again appeared to be at least one less intense line at $g \sim 1{\cdot}99$, contributing to the general asymmetry, but no others could be seen.

(*d*) *Spleen.* A very low concentration of spins was found in samples of this organ. It was noted that the apparent signal-to-noise ratio was improved by the integration technique[3]. The *g*-value of the signal found (2·002) appears to differ significantly from that of the other tissues mentioned so far. We could not detect any other lines in this spectrum, nor was there any obvious asymmetry.

(*e*) *Lung.* The low concentration of free radicals measured in this organ is the lowest mean value of the normal tissues measured in this series (with the exception of whole blood) and again the *g*-value appears to be significantly different from the others.

(*f*) *Muscle.* Only three results were taken for this tissue, but they were within the usual standard deviation of 25 per cent as found for other tissues.

Some tumour samples have also been examined (see Table 2). The majority of these show very little or absence of free radical signal above the limit of detection of our present system. They are thus smaller than our previously reported limits[1].

(*a*) *Metastasis of liver tumour in abdominal lymph nodes.* Samples from this tumour caused some surprise when they gave a large broad resonance line at $g = 2{\cdot}011$ and the suggestion of a low field line in the region of $g = 4$ (Fig. 4). No such signal had been reported before in any tumour at our normal cavity temperature of 37° C, although recent work by Brennan, Cole, Singley and Hodgkinson showed a complex spectrum in cancerous tissue at liquid nitrogen temperature (77° K)[4].

This signal was again found in other samples from the same metastasis and also for samples from an identical metastasis in another rat, the same result being obtained for the $g = 2{\cdot}011$ line but the low field signal being less evident.

(*b*) *Liver carcinoma induced by butter yellow (di-methyl aminoazobenzene).* After the discovery of the large broad lines in the metastases, samples of liver carcinoma, induced by butter yellow from two rats, were investigated for similar lines. No signals were observed from the apparently necrotic tissue of these tumours, but from the viable tissue this large resonance was again observed (Fig. 5). The low field resonance was not detected. The *g*-value and line width (2·016; 50 G), and the fact that no observable decay in intensity over a period of 24 h occurred at room temperature, seem to indicate that the signal is due to a paramagnetic ion rather than a free radical associated with the metabolic processes. It was not thought that the signal arose from some contamination in the carcinogen which induced the tumour, since the tumour had been transplanted through many generations of rats. Neither was any impurity suspected, since, as noted, no signal occurred in the necrotic tissue.

A search was made for similar signals in the viable tissue of the other tumour types investigated here, but no such lines were found.

This signal was not apparent in previous measurements[1] because of two factors. First, the line width is large and could possibly be missed if the field sweep was relatively small or of the same order, and secondly, the paramagnetic absorption from our early sample cells, which were of 'Pyrex' and not pure silica[1], appears to have hidden this line. However, the observation made before, that there appeared to be no free radical present in any detectable amount, seems to be further verified. It would, however, be difficult to resolve the comparatively small free radical signal that would be expected, from the large, broad resonance reported here.

(*c*) *Spontaneous kidney carcinoma.* This tumour was the only one in which an apparent free radical signal was observed. Although this signal was small, it was sufficiently large to make us confident of its existence (Fig. 3). It was not observed, however, in all the samples taken of this tumour type, but this may have been due to larger uncertain amounts of necrotic tissue present.

(*d*) *Other tumours.* A variety of other rat tumours (see Table 2) were investigated but yielded very small or no detectable signals, so that if free radicals are present as one would expect, their concentration is less than 10^{-7} moles./l.

The observations on free radical signals in normal tissues for the greater part merely establish facts about these tissues that previously had been observed only with liver, kidney and heart. The usefulness of these results is apparent when comparisons are made between normal and abnormal tissues of the same type.

The different g-values found for different tissues indicate that the source of the signals is most probably different in each tissue.

Beinert and Sands[5] and Bray, Petterson and Ehrenberg[6] have investigated the signals from the types of enzyme-substrate complexes found in rat liver and have shown the presence of both free radical and paramagnetic ion signals. The former is generally attributed by all to the formation of a semiquinone free radical in equilibrium, and the latter to molybdenum and iron of suitable valency, associated with the redox system. Since the mitochondria contain many such enzyme systems and since heart muscle mitochondrial particles have been shown

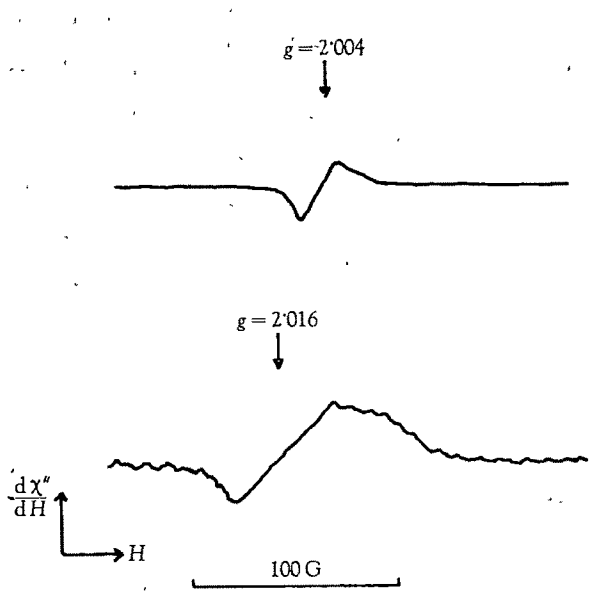

Fig. 5. Signal observed from liver carcinoma with (above) a representation of the normal rat liver signal on the same scale

to exhibit a similar signal[7], it would be expected that the signal observed would possibly be the envelope of a number of lines produced by the different active centres. The obvious conclusion is that this may account for the observed asymmetry in some of the signals discussed here. The problem is now to obtain the best fit to the envelope from linear combinations of a number of different free radicals of different g-values. At present the information is obviously too limited for such a process, but an assessment of the amount of each active system, associated with a measurement of g-values, might resolve these signals if this is the cause of the asymmetry. Other less intense lines are observed in fact as the modulation amplitude is reduced (see Fig. 2), but the resolution is poor. No change in overall line width or shape was noticed as the microwave power was reduced.

Noticeable, perhaps, is the apparent difference in g-values between the different tissues and also that those with the lowest g have been found to be least asymmetric. More precision in g-value measurements is required here.

The presence of the large paramagnetic absorption at $g = 2{\cdot}01$ (and possibly $g \sim 4$) from the rat liver tumours investigated is most interesting. (This was not observed in a recent communication by Vithayathil, Ternberg and Commoner[9], published after the preparation of this article.) It was thought that the presence of this signal in these tumours might have been due merely to an increase of a paramagnetic element in the system. Since this signal is not detectable in the normal liver, only a free radical signal being present, the signal obtained from tumour tissue is at least 100 times greater than any that might be present in the normal tissue. However, other methods of analysis on normal liver and liver tumours[8] show that for a number of typically paramagnetic species (in an ionized state), that is, copper, iron, molybdenum, manganese, the absolute concentration of these in the tumour is increased by only a factor of 2 above normal. The changes found in molar concentration from normal to tumour tissue by these workers are $4–8 \times 10^{-3}$ moles/l. for iron and $4–8 \times 10^{-4}$ moles/l. for copper. For molybdenum there is no change, the level remaining at about 2×10^{-5} moles/l. and likewise for manganese which remains at 4×10^{-4} moles/l.

Thus both iron and copper are present at levels several orders of magnitude greater in concentration than the paramagnetic species found in signals from rat liver tumours, and, if this signal is associated with the increase in concentration of one of these elements, then at least 1 part in 100 of this increase must be in a suitable valency state to give rise to this signal, as compared with only 1 part in 10^{-4} in the normal liver. In this case, the principal cause of the difference of signal between tumour and normal tissue need not be related to the actual increase in concentration of that particular element but more to a change in valency state. The implication of this is that some bound transition element in the normal liver cells experiences a valence change in the malignant cells (or perhaps is less tightly bound). The increased concentration of both copper and iron in these cells may or may not be related to this.

The g-value of the broad signal is similar to that found for Fe^{2+} and Mo^{5+} in various biological systems as described by other workers[5,6], and may be due to the presence of these. Since no hyperfine structure was detected and since the line was only 50 G wide, Mn^{++} was not thought to be contributing.

A programme of work is now in progress to separate the components of the cells contributing to the various signals in the overall pattern and to carry out activation analysis studies on the same samples measured in the electron spin resonance spectrometer.

We thank Dr. R. H. Thomlinson and Miss E. Craddock of the Medical Research Council Experimental Radiopathology Research Unit, Hammersmith Hospital, for supplying the tumour samples. We also thank the Scientific Research Council and the Medical Research Council

for the support of one of us (M. K.) and for providing the equipment.

ALPHA-RADIOACTIVITY OF HUMAN BLOOD

By V. HASSON and Dr. R. D. CHERRY
Department of Physics, University of Cape Town, Rondebosch, C.P., South Africa

MUCH attention has been paid in recent years to the problem of the natural radioactive content of human tissues. The development of a simple low-level α-counting technique[1] and a sensitive α-spectroscopic technique[2] by workers at the Royal Cancer Hospital has resulted in the accumulation of a large number of data by this group. The results most pertinent to the present discussion have been summarized by Mayneord *et al.*[3] and by Hill[4]. The total α-activity of normal human soft tissue was reported[3] at a level of about 7 pc./kg of wet tissue for most tissues, although values ranged from as low as 2 pc./kg in brain tissue to as high as 33 pc./kg in hair. The α-spectroscopic data[4] indicated that in many cases a large fraction of this activity was due to the nuclide polonium-210. Other workers have tended to concentrate on the measurement of specific nuclides rather than of total α-activity, but the results are in general agreement with the data quoted. Thus, polonium-210 concentrations in soft tissues ranging from 1 to 13 pc./kg have been reported[4–8], while radium-226 values of about 2 pc./kg[9,10] and less[4,11] are on record. Measurements of the activity due to the thorium series or to specific nuclides therein have sometimes been attempted. Such activity is generally detectable, but appears to contribute less than 50 per cent of the total α-activity[12].

The data referred to in the preceding paragraph were obtained from a variety of soft tissues such as lung, liver, kidney, spleen, muscle and hair. In addition, a great many data have been obtained from bone specimens, which tend to have an α-radioactivity of the order of twenty times that of soft tissues[3]. An important constituent of the human body which does not appear to have been investigated from the point of view of α-radioactivity is blood. A search through the literature revealed data by Gofman[13], who reported both uranium and thorium in human blood serum at his limits of detectability between 0·00 and 0·10 p.p.m., and a solitary value from a single blood sample by Hoffman[14], who quoted a uranium concentration of 10^{-10} g/ml. Several workers[1,15–17] have measured α-radioactivity in the blood of abnormally exposed persons (for example, radium dial painters and thorotrast patients), but we have not been able to find a record of any general survey of the α-radioactivity of normal human blood. The purpose of this article is to report the preliminary results of such a survey.

We made use of the α-counting technique of Turner *et al.*[1]. This involves a sealed sample-phosphor system of great sensitivity and convenience. The particular set-up used is essentially the same as that described in an earlier report from this laboratory[18]. The preparation of biological samples for thick-source α-counting usually requires some method of artificially concentrating the activity, and the method used must involve a process which results in (*a*) no contamination, (*b*) minimum loss of volatile trace elements, and (*c*) an end-product which is homogeneous (or easily homogenized by grinding). After investigation, the well-known freeze-drying technique[19] was found to be suitable for the blood samples used in the present investigation. In this technique the blood is initially frozen, and the process essentially involves the sublimation of moisture from the sample under vacuum. The blood comes into contact only with the surfaces of the containers in which it is stored and those in which the freeze-drying takes place (1·5-l. round-bottomed 'Pyrex' flasks in the present work); the risk of contamination is very small. The drying is usually performed at temperatures between $-10°$ and $-40°$ C (at most the temperature might rise to room temperature), and loss of trace elements by volatilization is thus minimized. The end-product is a dry, homogeneous powder which is easily ground in an agate mortar before packing on the phosphor for counting. Interpretation of results is simple and follows the usual 'thick-source' α-counting formula[1,20,21].

The blood samples used in this investigation consisted, in most cases, of expired blood from normal donors to the local blood transfusion service. As such, they contained additives in the form of standard anticoagulant chemicals, and it was necessary to correct for the α-radioactivity in these materials. This was measured, and the necessary small correction was made to all the results.

Checks on the results were made by:

(*A*) Sub-dividing eight samples into halves, and freeze-drying the two halves of each sample in two different containers. The total α-activities of the two halves of each sample were then measured separately. The average deviation from the mean was 8 per cent, and in no case was the deviation more than 20 per cent. Random contamination from containers would appear to be unimportant.

(*B*) Sub-dividing one sample into six batches, and adjusting the *p*H of each batch to values varying from 1·4 to 12·2 (compare a 'normal' *p*H of about 6·5 for citrated whole blood). The *p*H variation appeared to have no definite observable effect on the recorded α-activity, and we concluded that a *p*H dependent adsorption mechanism was unlikely to be a serious problem.

(*C*) Sub-dividing seventeen samples into two halves, then using one-half of each sample for a whole-blood measurement and centrifuging the other half to provide separate 'red cell' and 'plasma' volumes. The α-activities of the 'red cells' and the 'plasma' were then measured separately; these two results, combined together after suitable allowance for concentration factors, gave a whole-blood α-activity measurement which could be compared with the direct measurement. The results of this check are shown in Table 1. The errors quoted are those due to counting statistics only, and to each must be added an arbitrary error (of the order of 10 per cent of the activity) to allow for non-reproducibility in sample preparation. If this is taken into account, comparison of columns four and five of Table 1 shows that the agreement is reasonably good for most of the samples.

We feel that it is highly unlikely that we would have obtained such agreement if sample contamination were a major problem.

(*D*) As a final check, four of the samples (Nos. 14–17 in Table 1) were measured without the prior addition of anticoagulant. The activity values obtained for these samples do not appear to be appreciably different from those obtained for the other samples after applying the small anticoagulant correction.

The salient features of the results can be summarized as follows:

(1) The results shown in Table 1 represent our most carefully checked set of data, and they give a mean α-activity for the 17 samples of 54 pc./kg. The range of activities encountered covers a factor of about two both above and below this figure. In addition to the data shown in Table 1, we have measured the total α-activities of some forty other whole blood samples by the same technique. These have not been as carefully checked as the results in Table 1, but they confirm the relatively high value for the total α-radioactivity of blood which is quoted above.

(2) Our apparatus incorporated a second long-dead-time electromechanical register to record α-particle 'pairs'[1] due to successive decays from emanation-220 to polonium-216 to lead-212. This is made possible by the 0·16 sec half-life of polonium-216, and makes it possible to estimate the percentage of the total α-activity which is due to the thorium series. For all the whole blood samples measured, a striking feature was the high thorium-series percentages observed. In fact, if it is assumed that either radium-228 or thorium-228 is supporting the thorium series activity, then our results indicate that this series accounts for more than 90 per cent of the total α-activity in thirteen of the seventeen samples listed in Table 1, and for between 55 and 90 per cent of the activity in the other four samples. Because of the low 'pairs' rates involved the errors in the thorium series percentages are large as far as individual samples are concerned, but the overall picture of a high thorium series contribution seems to be unambiguous.

Table 1. TOTAL α-ACTIVITY OF HUMAN BLOOD IN PC./KG

Sample No	Red cells	Plasma	Whole blood: Derived from red cells and plasma	Whole blood: By direct measurement
1	82±6	77±4	80±5	61±5
2	82±6	31±2	56±4	55±5
3	70±5	31±2	50±4	54±2
4	93±6	26±2	59±4	55±5
5	62±6	20±2	37±4	44±5
6	43±4	29±1	34±2	40±4
7	75±6	26±1	44±4	66±5
8	77±5	29±2	44±4	45±4
9	114±7	42±2	70±5	82±5
10	55±5	83±2	72±4	55±4
11	125±7	42±2	81±5	109±5
12	55±5	36±4	40±4	79±7
13	33±6	29±2	32±4	39±4
14	43±5	35±2	39±4	69±4
15	34±5	33±2	33±4	34±4
16	36±5	40±2	38±4	42±4
17	47±4	49±4	48±4	40±2

(3) Comparison of columns two and three of Table 1 shows that the activity present in the red cells was greater than that in the plasma in fourteen of the seventeen cases—the average ratio (red cell activity)/(plasma activity) being equal to 1·71.

(4) Within the limits of reproducibility of our experimental technique, and of the number of samples analysed, we have not found any significant variation of α-activity level with either the blood group or the age of the donor.

Our present results are sufficiently different from those recorded on human soft tissues to require some comment. Most noteworthy, of course, is the fact that they indicate a blood α-activity level which is about seven or eight times larger than the average on record for most soft tissues. There are three possible explanations of this feature:

(*a*) Our results are substantially too high. We feel this is unlikely, in view of the care taken experimentally, the satisfactory checks carried out and the inherently non-contaminatory nature of the freeze-drying process. In view of the very low levels of activity involved, it is none-the-less highly desirable that our data be checked by other workers.

(*b*) The α-activity of blood is, in fact, substantially higher than that of muscle, liver, kidney, spleen, etc. It is difficult to see why this should be so, but our present lack of detailed knowledge concerning the metabolic fate of the α-emitting trace elements in the human body makes it impossible to rule out this possibility at this stage. Our results might even be construed as indicating that some nuclide supporting the thorium-series activity is, for some reason, retained in the blood rather than being transported to other tissues. Once again, such a conclusion can only be regarded as speculative at this stage.

(*c*) The results of previous workers are substantially too low. We intend to repeat measurements on various soft tissues utilizing the freeze-drying process; meanwhile, we can offer the following evidence as indicating that the possibility of previously reported values being too low does, in fact, have some experimental support: examination of the references quoted earlier shows that nearly all the data in the literature concerning the natural α-radioactivity of soft tissues were obtained from samples that were either ashed (at about 600° C) or wet-ashed (presumably at about 250° C). These processes were used either for the purpose of concentrating the activity to measurable levels or for chemical separations. They do, however, involve the risk of loss of volatile components, and several workers[13,23,24] have emphasized the serious nature of this risk where trace elements are involved; McDaniel *et al.*[23], in fact, particularly recommend that sample treatment be limited to 'mere lyophilization' (freeze-drying). We tested this possibility by unpacking three of our freeze-dried blood samples after counting and heating them for set periods at temperatures ranging from 100° C to 700° C. After determining the concentration factor involved at each temperature, the material was packed in the standard sealed sample-phosphor system and then counted after allowing the usual three to four week period for the samples to come back into a degree of radioactive equilibrium. The activity was then calculated, due allowance being made for the fact that the change in sample composition affects the α-particle range in the sample. It was immediately apparent that substantial losses (by a factor of two or more) occurred even on heating to 100° C, while those samples treated at the ashing temperatures in the vicinity of 600° C gave activity values which were lower than the freeze-dried values by factors as large as nine. It was also obvious that the degree of loss depended on other factors besides temperature—notably length of heating time—and that quantitative experiments would be difficult to reproduce accurately.

Also worthy of comment is the predominance of thorium-series activity which we have observed. This must in turn imply that the nuclide polonium-210 accounts for only a very small fraction of the total blood α-activity. Once again, this result is not in accord with the published data for human soft tissues.

The present work presents the preliminary results of a survey of the α-radioactivity of normal human blood. The activity values observed are surprisingly high, being several times higher than those previously reported for human soft tissues. Furthermore, they indicate a surprisingly high percentage of thorium series activity. If substantiated, these results raise intriguing problems concerning the disposition and metabolism of the α-radioactive trace elements in the human body. We hope that other workers in this field will check our results, and we commend to them the freeze-drying technique as a satisfactory method of sample preparation.

We thank Dr. N. E. Goodwin of the Western Province Blood Transfusion Service for supplying us with the blood samples, and acknowledge financial support from

the University of Cape Town, the Council for Scientific and Industrial Research and the Atomic Energy Board.

INTERLOCUS SPECIFICITY FOR CHEMICAL MUTAGENS IN *Aspergillus nidulans*

By DR. THOMAS ALDERSON and PROF. A. M. CLARK*
Department of Genetics, University of Cambridge

THE present paper reports preliminary observations of the apparent specificities of certain chemical mutagens towards various related gene loci in the fungus, *Aspergillus nidulans*. The mutagenic effects of two types of chemical compound are recorded, the monofunctional ethylating agents (diethyl sulphate and ethyl methanesulphonate), and the pyrolizidine alkaloids (heliotrine and lasiocarpine).

The mutational system used for study is one in which a methionine dependent strain of Aspergillus (*meth*$_1$; *bi*: requiring methionine and biotin) mutates by forward mutation to methionine independence after mutation at any of several independent suppressor gene loci[1]: the *meth*$_1$ suppressor mutations which have so far been tested are found not to be genetically linked to *meth*$_1$ (ref. 2).

Uninucleate and haploid conidia of the *meth*$_1$; *bi* strain give rise with a low frequency to methionine independent colonies when plated on a medium lacking methionine. Three of the revertant types (types *A*, *B* and *C*), which occur with the highest frequencies, and which are phenotypically distinguishable from one another, have been chosen for investigation. The type *A* suppressor forms a thinly growing green colony, the type *B* suppressor produces a brown pigment, and the type *C* suppressor forms a thick green colony with a hyaline edge; illustration of these three *meth*$_1$ revertant types is found in refs. 1 and 3. It is not known whether reversion occurs by back-mutation at the *meth*$_1$ locus, but if this occurs, the revertants are likely to show the essentially wild-type phenotype of the *meth*$_1$ type *A* suppressor class.

While genetical analysis[1,2] of both the *meth*$_1$ type *A* and *C* suppressor effects has shown that each phenotype is produced at either of two independent (and not closely linked) gene loci, technical difficulties have prevented the genetic resolution of the *meth*$_1$ type *B* suppressor effect. The *meth*$_1$ suppressor system thus covers the mutational response of several (at least five) gene loci, and allows the frequency of the three *meth*$_1$ suppressor phenotypes to be scored in one and the same experiment. However, as it is not possible to assign a mutant to a particular gene locus by phenotype alone, the *meth*$_1$ suppressor system is technically limited to scoring individual suppressor phenotypes, and these may, of course, show differential interlocus mutational specificities within themselves. Nevertheless, the results reported in the present investigation demonstrate a general differential specificity for mutation at the *meth*$_1$ suppressor loci after treatment with chemical mutagens.

* Present address: School of Biological Sciences, Bedford Park, Adelaide, Australia.

The techniques used are those at present in use in studies on *Aspergillus nidulans*[4].

Conidia for treatment were collected from 5-day-old plates and suspended in 0·2 M phosphate buffer (*p*H 7·0) containing 1 ml. of 0·1 per cent 'Tween-80' (a wetting agent) per 10 ml. of buffer, shaken in a Vortex mixer to break up conidial chains, and filtered through sterile cotton wool to remove mycelial debris.

Treatments were carried out at 37° C on a suspension of about 1–5 × 10^6 conidia per ml., either by pipetting in the reagent directly (as with diethyl sulphate, and ethyl methanesulphonate), or by re-suspending in the appropriate concentration of buffer plus reagent (as with lasiocarpine and heliotrine). After treatment, the conidia were washed by centrifuging and re-suspending in fresh buffer. Controls were handled in the same way. Viable counts were obtained by plating appropriate dilutions of the conidial suspension on to a medium supplemented with methionine and biotin; direct conidial counts were by haemocytometer. Mutants were assayed by pipetting samples of the conidial suspension into a methionineless-medium supplemented with biotin (at 45° C to prevent gelling) and poured on to Petri dishes barely to cover the surface of the plate. All cultures and plates were incubated at 37° C. The number of plates used for the assay of mutants is recorded for each experiment (Tables 1 and 2) to give an indication of the density of mutants per plate.

Total II (Tables 1 and 2) gives a corrected distribution for the type *A* and *B* suppressor phenotypes arising from an initial misclassification of a proportion of the type *A* revertants. A small number of apparent type *B* revertant colonies appeared atypically type *B*, in that, although they are darkly pigmented they conidiate green, unlike the majority of the type *B* suppressors. On transfer to a medium containing methionine, the pseudo-*B* type gives the type *A* phenotype, yet gives the pseudo-*B* phenotype when re-transferred on to a methionine-less medium. The proportion of pseudo-*B* phenotypes among type *A* varies between treatments (see Tables 1 and 2); the only mutagenic chemical which so far has not produced the pseudo-*B* phenotype is hydroxylamine[5].

Total III (Tables 1 and 2) is the correction for spontaneous mutation.

Spontaneous mutation. The rate of mutation from methionine dependence to methionine independence of the *meth*$_1$; *bi* strain is found to be about 1 × 10^{-6} (Table 1), with relative frequences of the type *A*, *B* and *C* phenotypes of 0·64, 0·36 and 0·09 × 10^{-6}, respectively, and overall percentages for the respective type *A*, *B* and *C* phenotypes of 59, 33 and 8.

It should be noted, however, that the spontaneous mutation rate and the overall percentages of *meth*$_1$ suppressor types reported by other workers for the *meth*$_1$; *bi* stock are at variance with the figure reported here. Thus Siddiqui records[3] (his Table 1, our calculation) a spontaneous mutation rate of $8{\cdot}2 \times 10^{-6}$, and overall percentages of *A*, *B* and *C* suppressor phenotypes of 34, 31 and 35, respectively. Furthermore, Lilly records a spontaneous mutation rate of 16×10^{-6} (ref. 1), with distributions of suppressor types[6] of 66 per cent type *A*, 31 per cent type *B*, and 3 per cent type *C* (based on 233 revertants). Roper reports[7] a spontaneous *meth*$_1$ suppressor mutation rate for the *meth*$_1$; *bi* stock held in his laboratory as about 10×10^{-6}, and this latter figure has been confirmed by us on his stock when plated under our conditions; a spontaneous mutation rate of $9{\cdot}2 \times 10^{-6}$, and a percentage distribution of the respective type *A*, *B* and *C* suppressor phenotypes (based on 199 revertants) of 35, 65 and zero.

Although there are pronounced disparities in the behaviour of the various *meth*$_1$; *bi* stocks, which, so far as is known, originated from a common stock in the Department of Genetics, Glasgow, our spontaneous *meth*$_1$ suppressor mutation rate is consistent (Table 1, and others). However, there is a statistically significant heterogeneity for the distribution of suppressor phenotypes between the controls in Table 1 ($\chi^2_{(12)} = 39$, $P < 0{\cdot}001$).

The monofunctional ethylating agents

Table 1 illustrates the mutagenic response of the *meth*$_1$ strain to the induction of type *A*, *B* and *C* suppressor phenotypes after treatment of conidia with diethyl sulphate and ethyl methanesulphonate; both treatments have been repeated several times over a range of conidial survival levels.

The ethyl methanesulphonate treatments (1–6) show a highly significant heterogeneity for the distribution of suppressor phenotypes ($\chi^2_{(10)} = 229$, $P \ll 0{\cdot}001$), as might be expected in treatments covering varying levels of conidial survival. However, there is still a significant heterogeneity in the distribution of suppressor phenotypes at similar levels of conidial survival; for example, the ethyl methanesulphonate treatments 1, 2 and 3, which are all at about the 50 per cent survival level, give a $\chi^2_{(4)} = 22$, $P < 0{\cdot}001$. The overall distribution of *meth*$_1$ suppressor phenotypes after ethyl methanesulphonate treatment shows a mutational response predominantly to the type *A* phenotype (92 per cent), with low responses to the type *B* (5 per cent) and type *C* (3 per cent) phenotypes.

The diethyl sulphate treatments (1–5) similarly show a highly significant heterogeneity in the distribution of the type *A*, *B* and *C* phenotypes ($\chi^2_{(8)} = 405$, $P \ll 0{\cdot}001$) over the recorded conidial survival levels.

At similar levels of conidial survival, the ethyl methanesulphonate (experiments EMS-5 and -6) and the diethyl sulphate treatments (experiments DES-2 and -3) show a significant difference in the distribution of suppressor phenotypes ($\chi^2_{(2)} = 22$, $P < 0{\cdot}001$).

The overall distribution of *meth*$_1$ suppressor phenotypes is significantly different for the control and diethyl sulphate ($\chi^2_{(2)} = 26{\cdot}5$, $P < 0{\cdot}001$), control and ethyl methanesulphonate ($\chi^2_{(2)} = 235$, $P \ll 0{\cdot}001$), and ethyl methane-

sulphonate and diethyl sulphate treatments ($\chi^2_{(2)} = 477$, $P \ll 0.001$).

The diethyl sulphate treatments show an overall distribution of *meth*$_1$ suppressor phenotypes which is different from the ethyl methanesulphonate treatments, that is, a 15·4 per cent decrease of the type *A* phenotype, and a corresponding increase in the type *B* phenotypes; there is no difference in their mutational response to the type *C* phenotype, but treatment with either ethylating agent shows a lower response to the type *C* phenotype that is found in the control experiments.

The pyrolizidine alkaloids[8]

Treatment of conidia with lasiocarpine and heliotrine induces two quite distinct and unrelated distributions for the *meth*$_1$ suppressor phenotypes. Lasiocarpine is found to give predominantly the type *B* suppressor phenotype (78 per cent) compared with the relatively low mutational response to this phenotype (13 per cent) produced by heliotrine. Correspondingly, heliotrine gives 85 per cent of the type *A* phenotype compared with the figure of 17·5 per cent produced by lasiocarpine; heliotrine also produces about half the percentage of the type *C* phenotype as lasiocarpine. Both distributions show highly significant heterogeneities, lasiocarpine ($\chi^2_{(6)} = 110$, $P \ll 0.001$), and heliotrine ($\chi^2_{(6)} = 50$, $P < 0.001$), with obviously significant deviations between their overall *meth*$_1$ suppressor distributions ($\chi^2_{(2)} = 122$, $P \ll 0.001$).

While the *meth*$_1$ suppressor distribution induced by lasiocarpine is clearly different from the other treatments recorded here, the distribution given by heliotrine deviates significantly from that of ethyl methanesulphonate ($\chi^2_{(2)} = 111$, $P \ll 0.001$), diethyl sulphate ($\chi^2_{(2)} = 70$, $P \ll 0.001$), and the control ($\chi^2_{(2)} = 67$, $P \ll 0.001$).

The various recorded mutagenic treatments obviously show striking interlocus specificities for the *meth*$_1$ suppressor phenotypes, despite the impracticability of assigning the mutant types to a particular gene locus; and despite the statistically significant heterogeneities of the *meth*$_1$ suppressor distributions after individual treatments. Further, the distinct variations shown in *meth*$_1$ suppressor phenotype distributions after treatment of conidia with such structurally similar chemicals as ethyl methanesulphonate and diethyl sulphate, on the one hand, and lasiocarpine and heliotrine[8], on the other, demonstrate the difficulties involved in assigning a common mutational mechanism to even closely related and assumedly functionally similar chemical mutagens. This consideration is heightened, if, as is claimed[8], the pyrolizidine alkaloids, in common with the ethylating agents, act by alkylation.

We thank Prof. J. M. Thoday for supplying the laboratory facilities, and the British Empire Cancer Campaign for Research for financial support.

PREPARATION AND PROPERTIES OF AN ENZYME SYSTEM FOR ETHYLENE PRODUCTION

By J. E. THOMPSON and PROF. MARY SPENCER
Departments of Plant Science and Biochemistry, University of Alberta, Edmonton, Canada

PREVIOUS studies[1–3] with several organisms have shown that ethylene is evolved from subcellular particles that have been partially disintegrated by such means as ageing *in vitro*. This paper reports the preparation and properties of enzyme powders capable of catalysing ethylene production, and such information, along with that obtained from experiments with enzyme inhibitors[4,5], makes it possible to propose a biosynthetic pathway for ethylene production.

Crude enzyme powders were prepared from subcellular fractions from oat seedlings, *Avena sativa*, wax bean seedlings, *Phaseolus vulgaris*, or wax bean cotyledons. Immediately before planting, the seeds were soaked for 10 min in 50 per cent sodium hypochlorite solution, washed in cold water, soaked for 5 min in 50 per cent ethanol solution and then rewashed. They were allowed to germinate and grow in the dark in previously sterilized flats of 'Perlite *R*' covered with wet tissue, or in 'California soil mix'. The seedlings were gathered at 8–10 days after planting and the cotyledons at 7–8 days. The latter tissue was used for most experiments because ethylene production was found to be maximal when the cotyledons were senescent (Fig. 1), and because mitochondria might be expected to undergo a decrease in activity and number at this stage[7]. (Disintegration of mitochondria in intact fruits[8] coincides with the period of maximum ethylene evolution, and *in vitro* production of the gas has been shown to be associated with mitochondrial disruption[1].)

For preparation of the enzyme powders, the whole seedlings were frozen at −15° C overnight, then ground for 15 sec in ice-cold buffer (0·5 M sucrose, 0·2 M potassium hydrogen phosphate, *p*H adjusted to 7 with sodium hydroxide) at low speed in a Waring blender, strained through cheese cloth and centrifuged at 0° C at 4,080*g* for 10 min. The supernatant was then recentrifuged at 35,000*g* for 15 min. When only cotyledons were used, they were crushed in a hydraulic press at 20,000 p.s.i. in ice-cold sucrose–phosphate buffer of the above composition, then strained and centrifuged in the same manner as the crushed seedlings. The method used for tissue grinding was found to be very critical. If the treatment with the blender was too severe, activity was greatly reduced and sometimes completely lost. Crushing the tissue hydraulically, as was done with the frozen cotyledons,

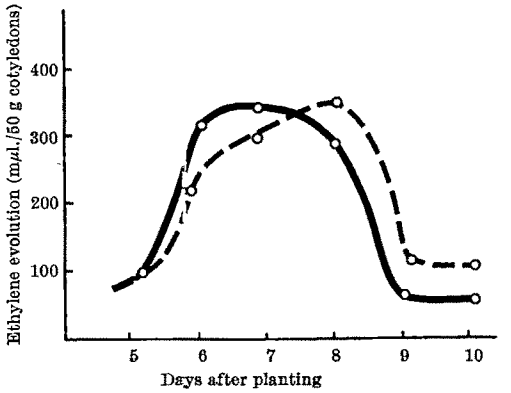

Fig. 1. Ethylene production by bean cotyledons: 0–2 h after harvest (————); 2–4 h after harvest (– – – –)

Crude powder was from a different batch preparation than the fractions.
N = not detectable.
Reaction mixtures: all samples contained 0·5 M sucrose–0 125 M phosphate buffer *p*H 7·0, 1 5 mM ATP, 50 mM β-alanine, 2·0 mM TPP, 1 0 mM Mg^{2+} added as $MgSO_4$, 0·17 mM Co*A*. The 65–100 per cent fraction contained 0·5 mM pyridoxal phosphate and 0·2 mM Fe^{3+} added as $Fe_2(SO_4)_3$. (Other experiments have shown that the 0–20 per cent fraction is inactive on addition of pyridoxal phosphate and Fe^{3+}.)

has been found to be a less drastic treatment giving a greater yield of structurally intact mitochondria. With both preparations, the pellet obtained from the second centrifugation was suspended in cold deionized water, then frozen in a dry ice–acetone bath and thawed in a 40° C water bath three times., This suspension was then subjected to ammonium sulphate ($(NH_4)_2SO_4$) fractional precipitation. Cold saturated ammonium sulphate solution, brought to *p*H 8·0 with sodium hydroxide, was used, and the fraction that separated after 1·5 h at 5° C at 66 per cent saturation with ammonium sulphate was lyophilized, and in the presence of β-alanine and ATP was active in ethylene production. (The supernatant fraction was only slightly active under these conditions.)

Lipids were then removed from the crude powder by a butanol extraction. To achieve this, the powder was suspended in cold absolute *n*-butanol (50 ml./g of powder) by use of a Servall 'Omnimixer' set at low speed, for 30 min; the suspension was centrifuged at 18,800*g* for 10 min at 0° C and the supernatant discarded. The residue was again treated with butanol and centrifuged as above. The precipitate was partially dried on filter paper under suction, in an atmosphere of nitrogen.

Further purification was obtained by intensive ammonium sulphate fractionation. The material on the filter paper was suspended in cold deionized water (10 ml. water/g of initial crude powder) for 5 min before addition of ammonium sulphate. All ammonium sulphate fractions were allowed to aggregate at 5° C and were subsequently spun down at 18,800*g* for 10 min at 0° C. The 0–20 per cent fraction was inactive in ethylene production and the 20–65 per cent fraction was active. The supernatant, after dialysis against deionized water for 24 h, was lyophilized, yielding the 65–100 per cent fraction. It is evident from Table 1 that this fraction was considerably more active with respect to ethylene evolution than the original crude powder. In subsequent experiments, a 35–100 per cent fraction was used in order to incorporate a large portion of the activity.

Collections and determinations of ethylene were conducted as previously described[1,6] except that in the gas chromatographic analyses for ethylene, 50 × 0·35 cm columns of activated alumina coated with silicone ('Burrell 341-116-02') were sometimes used instead of columns of squalane-coated firebrick.

When ^{14}C-labelled ethylene was used, it was collected in mercuric perchlorate and the radioactivity determined with a 'Nuclear-Chicago' liquid scintillation unit, Model 725, operated at 5° C. Mercuric perchlorate, containing the labelled gas as a mercury–ethylene complex, was mixed with anthracene and 'Tween 81' in the ratio 3 g anthracene : 2 ml. perchlorate : 1 drop 'Tween 81'. The mixture was stirred to a dry paste and counted.

β-alanine, together with the cofactors pyridoxal phosphate and ferric ion (Fe^{3+}) for transamination, and thiamine pyrophosphate (TPP) and magnesium ion (Mg^{2+}) for decarboxylation, when added to the enzyme powders yielded ethylene. Table 2 illustrates typical results obtained with crude powders. β-alanine augmented ethylene production by approximately 35 per cent relative to a control of crude powder and ATP. β-alanine, TPP and Mg^{2+} increased ethylene production by approximately 18 per cent relative to the same control containing crude powder and ATP. Addition of nicotine adenine dinucleotide (NAD) to β-alanine, TPP, Mg^{2+}, ATP and crude powder, inhibited production by approximately 25 per cent; hence it appeared that a transaminase rather than a deaminase was active. Pyridoxal phosphate did not in itself extensively augment emanation. It is possible that substantial amounts of this cofactor remained tightly bound within the system throughout the preparation of the crude enzyme powder. A system of β-alanine, TPP, Mg^{2+}, coenzyme *A* (Co*A*) and ATP increased ethylene production by approximately 41 per cent relative to a control containing crude powder and ATP.

Reaction mixtures: 1*A* and 2*A*: 0·5 M sucrose, 0·125 M phosphate buffer *p*H 7, 1·5 mM ATP. All other samples had 50 mM β-alanine in addition; 1*C*, 1*D* and 2*B* contained 2·0 mM TPP, 1·0 mM Mg^{2+} added as $MgSO_4$; sample 1*D* was 0 005 mM in NAD and 2*B* 0·17 mM in Co*A*.

The purified powder, in the presence of appropriate cofactors and substrates, produced a substantial amount of ethylene, but in the absence of these materials, the same weight of powder was essentially inactive (Table 3). No ethylene was produced by a mixture of substrates and cofactors in the absence of enzyme powder. Addition of α-ketoglutarate (αKG) to a system containing ATP, β-alanine, TPP, Mg^{2+}, pyridoxal phosphate, Fe^{3+} and Co*A* augmented production by 40 per cent, and addition of malonic acid caused an 83 per cent increase in ethylene evolution. Lipoic acid decreased production by 73 per cent, suggesting that the decarboxylation was probably non-oxidative.

When β-alanine-2-^{14}C was added to a complete reaction mixture, labelled ethylene was obtained as indicated in Table 3. Other experiments showed that production of ethylene was not affected by the presence or absence of sucrose.

The ethylene-producing activity of the enzyme preparations decreased markedly with time, and 2 weeks storage in a desiccator at 5° C rendered the powders essentially inactive. Furthermore, the system was found to be sensitive to small differences in *p*H, being virtually inactive outside the range 6·7–7·2.

In purification of the enzyme powders, it was necessary, before lyophilization, to dialyse the 35–100 per cent ammonium sulphate fraction. To replace losses during dialyses, in addition to required substrates and cofactors, αKG was introduced as an amino group acceptor.

(When α-ketoglutarate or malonate was added, it was necessary to adjust the reaction mixture to pH 7·0 with sodium hydroxide).

A possible pathway for the conversion of β-alanine to ethylene is the following:

Malonic semi-aldehyde is very unstable and could quickly go to either β-hydroxypropionic acid or malonic acid. It is suspected that the large boost in ethylene production on addition of malonic acid arises from a shift in equilibria favouring production of β-hydroxypropionic acid.

Addition of 90 μc. of labelled β-alanine to purified powder, substrates and cofactors yielded labelled ethylene. In this experiment, unlabelled β-alanine was reduced to 20 per cent of its normal molarity to lessen the dilution of the label. The lower specific activity of the 21–24 h collection compared to the initial production (Table 3) may implicate adjustment of the equilibria allowing conversion of malonic acid to malonic semi-aldehyde, rather than β-alanine to malonic semi-aldehyde. It is significant that the per cent conversion of label (0·001 per cent) was comparable to the molar conversion of β-alanine to ethylene; about half the ethylene produced was labelled. Preliminary identification of intermediates further supports the proposed pathway.

Additional evidence that β-alanine may be a precursor of ethylene came from other experiments, when production of the gas was obtained non-enzymatically by a heat-catalysed Snell reaction among β-alanine, pyridoxal hydrochloride and cupric ion.

LOCATION OF THE MECHANISM OF ACTIVE TRANSPORT OF SODIUM ACROSS THE FROG SKIN

By CATALINA A. ROTUNNO, DR. MARÍA ISABEL POUCHAN
AND
PROF. MARCELINO CEREIJIDO
Departamento de Físico-Química, Facultad de Farmacia y Bioquímica, Buenos Aires

THE past 10 years, since Koefoed-Johnson and Ussing[1] introduced a model of ion transport, have seen a considerable increase in our knowledge of the properties of the epithelial membranes. This model assumes that net Na^+ transport across frog skin consists of two main steps: a passive diffusion through an outer barrier and an active transport across an inner barrier. The model also assumes that the outer barrier is almost impermeable to K^+. Since Meyer and Bernfeld[2], as well as Ussing[3], suggested that the seat of the skin electrical potentials and salt-transporting mechanism was located in the cells of the stratum germinativum, the inner and outer barrier of the model would be identified as the inner and outer facing membranes of these cells. However, Kidder, Cereijido and Curran[4], on the basis of electrical potentials changes following a change in Na^+ concentration in the outer solution, demonstrated that an Na^+-sensitive barrier appears to be located at the outer border of the skin. This information, together with the observation of Curran and Cereijido[5] that all the K^+ in the skin exchanges with potassium-42 in the inside solution with apparently a single time constant, would suggest that the outer

barrier of the Koefoed-Johnson and Ussing model is located near the anatomical outer border of the skin. With respect to the mechanism by which Na^+ crosses that barrier Cereijido, Herrera, Flanigan and Curran[6] have clearly shown that it is not entirely by simple diffusion; instead, Na^+ interacts with the membrane. The present article deals with the location and properties of the outer barrier as well as the location of the Na^+-active transport mechanism. It will be shown that Na^+ entrance to the cell across the outer barrier involves an active mechanism and that there exists at that level, and across the whole epithelial layer, a sodium–potassium activated adenosine-triphosphatase (Na–K ATPase) which may constitute the molecular basis of the Na^+ active transport.

The abdominal skin of *Leptodactylus ocellatus* was mounted as a flat sheet between 'Lucite' chambers (3·14 cm^2 area) and bathed with Ringer's solution containing 1–10 mM Na^+ (sodium sulphate–sodium bicarbonate) on the outside and 120 mM on the inside. Both Ringer's solutions contained 2 mM K^+ (potassium sulphate), 250 mg/l. calcium sulphate, 2·4 mM HCO_3^-. Sucrose was added to the outside Ringer's solution in order to adjust the osmolarity to 188 mosm, and on both sides air was bubbled through the Ringer's solutions to give a *p*H of 8·2. In this preparation the short-circuit current measures the Na^+ net flux when sulphate Ringer's solutions are used[7]. In nine experiments the Na^+ net flux was 0·50 ± 0·07 (mean ± 1 standard error) μmol. h^{-1} cm^{-2}, which indicates that the skin is able to transport Na^+ from a solution with a concentration of 1–10 mM Na^+. In a second group of skins treated in the same way, ^{14}C-inulin was added to the inside solution to measure the inner extracellular space. After an hour the skins were removed from the chamber, blotted, and 2·67 cm^2 of the exposed area in the chamber cut out with a cork borer and weighed. The portions of skin were then allowed to dry to a constant weight at 90° C and the difference between the wet weight and the dry weight taken as the total water. Na^+ and ^{14}C-inulin were extracted with 2·0 ml. of 0·1 N nitric acid and measured. With these data and the concentration of Na^+ and ^{14}C-inulin in the bathing solutions the concentration of Na^+ in the cell was computed. Since in another set of skins with ^{14}C-inulin added to the outside solution the outer extracellular space was found to be between 0·1 and 0·3 μl. cm^{-2}, and because the Na^+ concentration in the outside solution never exceeded 10 mM, no correction was made for the amount of Na^+ contained in this space. Table 1 shows the values of the wet weight, the extracellular space, the percentage of water and the Na^+ content. In fifteen experiments in which these parameters were measured in the same piece of tissue, the Na^+ concentration in the cells was 97·0 ± 4·8 mM. It was possible to compute a similar value from data published by Huf, Doss and Wills[8]. Using *Rana pipiens*, they found 346 μmoles of Na^+ per gram of dry skin and a water content of 74·6 per cent. Since the Na^+ concentration in the Ringer's solution was 119 mM, assuming that, as in our experiments, 28·2 per cent of that water was in the epithelial cells, the concentration of Na^+ in the cells was 114 mM. Therefore the Na^+ net flux from the outer solution to the cells occurs against a concentration gradient. However, Cereijido and Curran[9], using microelectrodes, demonstrated that under short-circuited conditions in sulphate Ringer's solution the skin maintained an electrical potential difference of −18 mV (cell negative), that is, was oriented in the direction which 'helped' Na^+ to enter the cell compartment. Then, if Na^+ was to have entered this compartment by a passive process, its concentration in the cell water should have been at the most $10.e^{-18\ F/RT} = 20{\cdot}4$ mM, which is far below the actual concentration measured. It is concluded that an active mechanism must be operating at the outside solution-cell boundary.

An Na–K ATPase associated with ion transport was found in many tissues[10]. Bonting and Caravaggio[11] demonstrated the presence of a sodium–potassium-dependent, ouabain-sensitive ATPase activity in homogenates of frog skin. Farquhar and Palade[12] demonstrated histochemically that ATPase activity was associated with all cell membranes facing the intercellular spaces, including the cell membranes of the outermost epithelial layer. This ATPase, however, is not necessarily the sodium–potassium-dependent one. The relationship between these ATPases was therefore studied in an effort to determine whether there is any Na–K ATPase activity near the outermost cell layer of the skin where an active mechanism was found. The skin was placed on the stage of a freezing microtome with the outer surface facing up; it was then frozen and a cylinder of 2·00 cm^2 base area was cut by means of a cork borer. The cylindrical piece of tissue was then sliced, and an effort was made to obtain slices covering the whole area. The ATPase activity and proteins were measured in each slice. Determination of ATPase activity was based on the method of Lowry *et al.*[13]. The assays were performed in triplicate at 40° C using two incubation media the only difference in which was that one had 5 mM K^+ and the other had 10 mM ouabain. The difference in activity was taken as ouabain-sensitive (or sodium–potassium-dependent) ATPase. Since the Q_{10} of this enzyme is 1·9 (see ref. 11) the values were corrected for 20° C. Proteins were measured according to the method of Lowry *et al.*[14], and the amount of protein per unit area was thus calculated. Table 2 shows the distribution of Na–K ATPase specific activity expressed as μmoles of inorganic phosphate liberated per mg of protein and per hour across the 'normalized depth' at which the slice was obtained; the outer border of the skin was taken as the zero reference. The 'normalized depth' was obtained as follows: the amount of protein measured in a given slice was added to the amount measured in all previous slices (that is, between the outer border and the given slice). This value was divided by the total amount of protein which in turn was obtained by adding together the amounts contained in all the individual slices. The fraction obtained was considered to be a measure of the depth. The slices came from eight different skins. Each of the figures in the column on the right represents a mean value of all those slices obtained at the same range of normalized depth. Na–K ATPase seems to be evenly distributed across the whole skin with a mean value of 0·182 μmole/h/mg of protein. Since 3·38 mg cm^{-2} of protein was present, the total amount of Na–K ATPase activity was 0·72 μmole h^{-1} cm^{-2}.

The stoichiometry between the active transport of Na^+ and the hydrolysis of ATP due to the Na–K ATPase was found to be close to three Na^+ ions actively transported per energy-rich phosphate bond split[11,15–17]. If the active transport mechanism is to pump three Na^+ ions per molecule of ATP split, 0·167 μmole of ATP would be needed per hour and per square centimetre in order to account for the net flux. From the data presented in Table 2, it is clear that this amount of ATP can be hydrolysed by the ATPase contained in a band covering the

* Total thickness.

† Total amount of protein per square centimetre of membrane.

outer 28·2 per cent of the total thickness. If we take the relation cell water/total water as an equivalent to the relation cell/total tissue, then the cells occupy 28·2 per cent of the total thickness—a figure which agrees remarkably well with the area needed to satisfy the Na–K ATPase requirement (see Table 1). This estimate rests on the assumption that the assay method measures the whole enzyme activity in the tissue and that the proteins are homogeneously distributed. If this were not so, the amount of Na–K ATPase needed for the net sodium transport would be contained in a narrower band of tissue and only the outermost layers of the epithelium would actually participate in the process.

Recent investigations by Snell and Chowdhury[18] suggest that the electrical profile of the frog skin is a linear function of distance across the epithelial cell layers, and that the contralateral effect of Na^+ and K^+ on the potential is mediated by their primary effects on the Na^+ transport system. The homogeneous distribution of Na–K ATPase through the epithelium, together with recent observations that the active sodium transport mechanism is electrogenic[5,19], lend strong support to the suggestion made by Snell and Chowdhury. This is a somewhat puzzling conclusion: while the electrochemical potential gradient between the sodium in the outer solution and in the cells is not explained on the basis of a passive distribution and requires an active step, the pumping mechanism is distributed over the whole epithelium. An alternative explanation would be a 'compartmentalization' of sodium. This agrees with the observation[20] that only a small fraction (less than 10 per cent) of the total sodium in the cells participates in the transport of this ion.

FINE STRUCTURAL LOCALIZATION OF NORADRENALINE IN VESICLES OF AUTONOMIC NERVE ENDINGS

By Dr. FLOYD E. BLOOM* and Prof. RUSSELL J. BARRNETT
Department of Anatomy, Yale University School of Medicine, New Haven, Connecticut

SEVERAL electron microscopic investigations[1–3] have confirmed the usefulness of the histochemical reaction by which primary glutaraldehyde fixation and subsequent exposure of adrenal medullary cells to one of several metal-containing oxidizing agents, such as dichromate[4], ammoniacal silver[5] or osmium tetroxide[6], can be used for the selective production of electron density in noradrenaline-containing granules. In medullary tissue subjected to this histochemical reaction[7], nerve endings on chromaffin cells were found to contain granular material of slight density within large synaptic vesicles. The latter are in the size range of similar structures reported in previous fine structural studies of hypothalamus, brain stem, spinal cord and pineal gland, after a variety of preparative techniques. The failure of the semi-dense material in the medullary nerve ending vesicles to react equivalently to the chromaffin cell noradrenaline-containing granules after the above reactions jeopardizes the possible correlation of so-called 'dense core' synaptic vesicles with the storage site of noradrenaline in nerve endings.

In our experiments we have utilized an oxidative histochemical reaction[4] in combination with the specific noradrenaline-depleting action of α-methyl metatyrosine (AMMT)[8] and the less specific depletory action of reserpine[9], to compare and characterize the reactivity of rat medullary chromaffin noradrenaline-containing granules with the nerve ending 'dense core' vesicles in both adrenal medulla and vas deferens. The latter structure has nerve fibres which are strongly fluorescent for noradrenaline[10], and extensive pharmacological data suggest a functional role for noradrenaline in the vas[11]. Richardson, who utilized this organ for his original description of autonomic nerve ending fine structure[12], observed a high percentage of 'dense core' vesicles in these endings after fixation with osmium tetroxide.

Normal, untreated, adult albino rats and litter mates treated with either AMMT (150 mg/kg), given intravenously 12–14 h previously, or with two intra-peritoneal injections of reserpine (2·5 mg/kg), given 24 and 4 h before killing, were anaesthetized with 'Nembutal' (25 mg/kg). One vas deferens and both adrenal glands were quickly excised and immersed in 5 per cent glutaraldehyde buffered to *p*H 7·4 with phosphate[13]. While immersed, the adrenal cortices were removed by trimming, and 1–2-mm thick longitudinal, transverse sections of vas were prepared. After a total fixation of 2 h, half the tissue blocks were incubated in 2·5 per cent potassium dichromate[4] in the phosphate buffer (*p*H 7·0) for 2 h and then refixed in phosphate-buffered 1 per cent osmium tetroxide for 1 h. The other half of the blocks were refixed in the buffered 1 per cent osmium tetroxide for 4 h directly after the glutaraldehyde, without an intervening dichromate oxidation. Routine ethanol dehydration and embedment in maraglass—'*D.E.R.* 732' (ref. 14)—followed the fixation; thin sections, cut on an '*LKB*' ultratome, were examined in an *RCA* '*EMU*' 3-*F* electron microscope. Some of the thin sections were exposed to saturated uranyl acetate to enhance the contrast of cellular membranes.

In confirmation of the previous results, both of the foregoing reaction protocols (oxidation with dichromate or osmium) revealed two types of chromaffin cell granules on the basis of their electron density. The majority of cells had membrane-bounded granules of only slight or moderate electron density and corresponded to adrenaline-containing cells. Fewer cells, scattered in groups, con-

* Special postdoctoral fellow, National Institute of Mental Health, National Institutes of Health, Department of Health, Education and Welfare.

tained membrane-bounded granules which were extremely electron-dense after either oxidative procedure, and these were considered to be the noradrenaline-containing cells. Nerve endings, which contained two types of synaptic vesicles, abutted on both types of cells. The majority of the vesicles, 300–500 Å in diameter, contained clear contents, while a few were larger (400–800 Å) and contained a core of material which showed only slight density after reaction with oxidizing agents (Fig. 4). For comparison, the density of the contents of the larger vesicles, which were usually observed at the perimeter of the axoplasm of the endings, was closer to the density developed in the epinephrine-contained granules and was distinctly less dense than the noradrenaline-containing granules of chromaffin cells. This material contained in vesicles of a synaptic ending was, therefore, considered unreactive for noradrenaline.

After fixation in glutaraldehyde and subsequent oxidative reaction, the nerve endings of the vas deferens were found to contain 'dense core' vesicles 400–900 Å in size, uniformly distributed throughout the ending (Fig. 1). The contents of these vesicles were intensely reactive histochemically and, therefore, electron-dense, and this type constituted about 80 per cent of the vesicles observed in normal endings. The remainder were electron-lucent vesicles, which were of the same size range as the above-described, reactive 'dense core' vesicles. The material made dense by oxidation in the vesicles was roughly equivalent in density to that of the noradrenaline-containing granules of chromaffin cells. Following either the reserpine or AMMT treatments, the nerve ending of the vas deferens contained few or no 'dense core' granules within the synaptic vesicles (Figs. 2–3). In micrographs of more than 100 nerve endings of the treated animals, only 1–7 per cent of the vesicles contained sparse, dense-

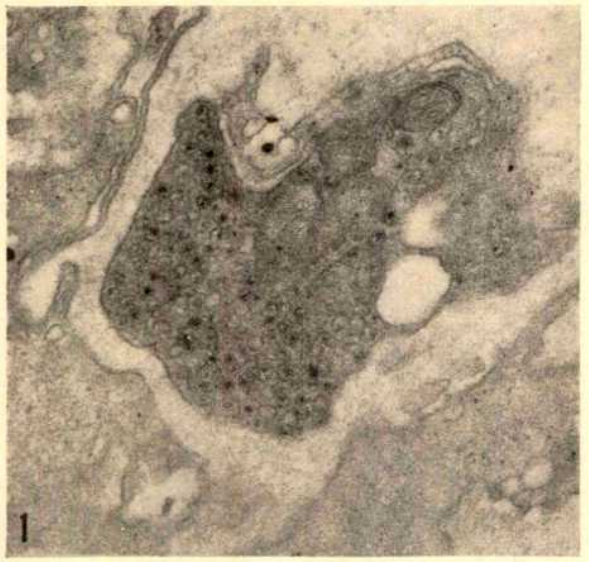

Fig. 1. Autonomic nerve ending in rat vas deferens. Contents of most synaptic vesicles appear dense due to dichromate oxidation (×50,000)

Fig. 2. Autonomic nerve ending in vas deferens of rat tested with reserpine. Despite prolonged osmium oxidation, little or no dense material occurs in synaptic vesicles (×50,000)

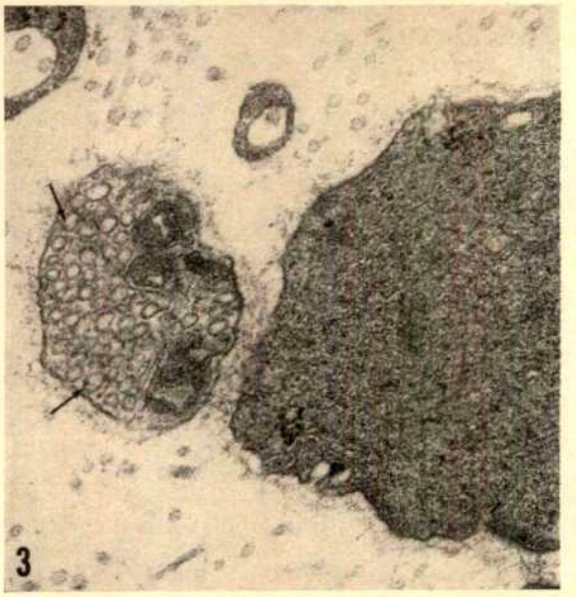

Fig. 3. Autonomic nerve ending in vas deferens of rat treated with α-methyl meta-tyrosine. Despite dichromate oxidation, only little dense material occurs in synaptic vesicles (arrows) (×50,000)

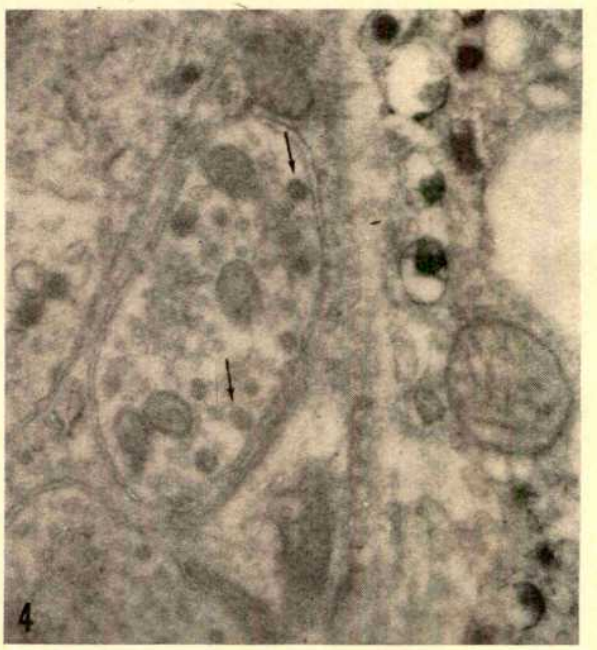

Fig. 4. Autonomic nerve ending on norepinephrine-containing cell of adrenal medulla of rat treated with α-meta-tyrosine. Although drug treatment markedly decreased granular content made dense by oxidation with dichromate, no such effect was noted on large synaptic vesicles (arrows) whose contents were not reactive with dichromate (×25,000)

staining contents, usually distributed in a spotty fashion in relation to the membranous envelope. However, the total number of vesicles was similar to that found in the vas of untreated animals. In the nerve endings of the treated animals the few vesicles containing some dense material were found surrounded by vesicles with clear contents, as though depleted of their reactive material. Although the depletor drug treatments caused fragmentation and partial or complete evacuation of the dense noradrenaline-containing granules in the medullary cells, the unreactive, semi-dense core material in vesicles of nerve ending of the medulla were unchanged in either density or number (Fig. 4). There was also no apparent reduction in the total number of vesicles in these nerve endings as a result of drug treatment.

These results indicate that the 'dense core' granules contained within the synaptic vesicles in presumably adrenergic vas deferens nerve endings demonstrate, as a result of a selective histochemical reaction, an electron density equal to that of noradrenaline-containing chromaffin cell granules in the adrenal medulla. However, all granular material within synaptic vesicles does not give a positive reaction (increase in density after oxidation with dichromate osmium tetroxide), as shown by the 'non-reactivity' of those 'dense core' vesicles in the presumably cholinergic nerve endings on the same chromaffin cells showing reactive noradrenaline-containing granules. That this is a substantive difference and not one related to the concentration of the amine bound within the vesicles is confirmed by the depletion experiments. When the animals were given a drug (AMMT or reserpine) capable of depleting normal stores of noradrenaline, the 'dense core' granules in synaptic vesicles of the vas are depleted either partially or completely, while the semi-dense material with 'dense core' synaptic vesicles of the medullary nerve endings remained unchanged. Since the semi-dense material in the latter vesicles was not influenced by reserpine treatment, which also depletes serotonin and dopamine, an even wider histochemical-pharmacological separation between these two types of granular material contained within vesicles is likely. While either dopamine or serotonin is capable of reducing metallic-containing oxidants[15] to produce density, these amines, not present in the vas, could interfere with interpretation in other neural areas where all three biogenic amines are present. However, AMMT, which presumably depletes only noradrenaline after the interval of time used, is likely to be of greater utility in ultrastructural neuropharmacological studies by increasing the specificity of the noradrenaline identification by subtraction of stored, histochemically-reactive, granular material.

The present results are most compatible with those of Wolfe *et al.*[16], whose electron microscopic autoradiographic localization of tritiated noradrenaline in nerve endings of the rat pineal indicated that the dense material of 'dense core' granules within these synaptic vesicles was due to the amine itself. A logical extension of these data would be to include the macromolecular binding matrix within the granules as an additional possible source of density (on histochemical reaction), which might be expected to fluctuate with storage and release of the amine[17]. Recent suggestions that the 'dense core' granules within synaptic vesicles may represent forms of lysosomes[18], or that their internal density is due to a lipoprotein similar to that forming the membranous structures[19], need be less seriously considered. The identity and function of the semi-dense unreactive material in some synaptic vesicles remain to be explained. In addition, this finding suggests that a blanket association of dense material within synaptic vesicles with biogenic amines should be viewed with caution. Further details on the specificity of the histochemical reactions, with more extensive pharmacological experimentation, will appear separately. This combined pharmacological and fine structural histochemical approach is at present being applied to a variety of nerve-ending sites within the central nervous system.

EFFECT OF SPORIDESMIN ON LIPID METABOLISM IN RABBITS

By J. ANDREW PETERS

Fats Research Division, Department of Scientific and Industrial Research, Wellington, New Zealand

SPORIDESMIN, a highly toxic metabolic product of the fungus *Pithomyces chartarum*, is considered to be the causative agent of facial eczema, a liver disease in sheep and cattle in New Zealand and Australia[1].

The pathological changes that occur as the disease progresses have been described by Mortimer[2], who also noted that similar pathological changes could be produced in rabbits, guinea-pigs and rats. One of the prominent biochemical features of the enterohepatic disturbances preceding biliary obstruction is an accumulation of liver triglycerides, which was interpreted as a malfunction of the hepatic triglyceride-secreting mechanism[3,4].

It was of interest to know whether this type of mechanism, as the result of sporidesmin intoxication, also occurs in non-ruminants. If this were the case it would, for reasons of animal accommodation and economy, be more expedient to use small laboratory animals in order to investigate, in greater detail, this type of deranged lipid metabolism. This article describes the changes in serum and liver lipids in rabbits during the period of 48 h following dosing with sporidesmin. In addition, consideration is given to the disturbances associated with biliary obstruction.

Crystalline sporidesmin-benzene complex was obtained from the Ruakura Animal Research Station, Department of Agriculture, New Zealand. Immediately before use the complex was dissolved in a small volume of ethanol, and this solution was diluted with distilled water. The final preparation contained 0·5 per cent ethanol and 0·25 mg sporidesmin per ml. Eighteen virgin female rabbits (2·1–3·4 kg, 6–7 months old) were divided into three groups of six animals. After fasting overnight, each animal in two of the groups received an oral dose of 1 mg/kg body-weight of sporidesmin by stomach tube

under light ether anaesthesia. Similarly, each animal in the third (control) group received an equivalent dose of distilled water. The fasting animals of one sporidesmin-dosed group, and those of the control group, were killed 24 h after dosing. Those of the remaining sporidesmin-dosed group were killed 48 h after dosing. The animals were bled under 'Nembutal' anaesthesia from a polythene cannula inserted into a carotid artery, and their livers excised immediately after death. Sera and livers were frozen as described[4].

Within 4 h after bleeding, non-esterified fatty acids were determined[5]. Serum lipid extracts[6] and liver lipid extracts[4] were prepared, and their cholesterol esters, triglycerides, cholesterol and phospholipids compositions determined by means of a quantitative thin-layer chromatography procedure[7]. The results of this investigation are summarized in Table 1.

Despite the wide range of compositions of the serum and liver lipids, certain general conclusions are justified which lend support to earlier suggestions[3,4]. The action of sporidesmin resembles that of other hepatotoxins[8,9] in producing a high elevation of liver triglyceride levels within 24 h, which then subsides to considerably lower levels at 48 h after dosing. However, no concomitant hypotriglyceridaemia is observed. It is conceivable, therefore, that sporidesmin poisoning inhibits not only the mechanism of triglyceride exit from the liver, but also, to a greater extent, the mechanism which regulates triglyceride uptake from the circulation into adipose tissue. The net result is that the serum triglyceride levels are elevated at the 24 h stage. Diminished lipoprotein lipase activity could possibly be responsible for this rise.

If the accumulation of triglycerides in the liver were due to an increased release of fatty acids from the adipose tissue (for references see Henderson[10]) a rise in serum non-esterified fatty acid level would be observed. Since sporidesmin induces not only a fall in the serum non-esterified fatty acid levels, but also a rise in the serum triglyceride levels, other factors, not directly associated with lipid transport, are involved which subsequently lead to the accumulation of liver triglycerides. In fact, there is evidence that the fatty liver, induced by the action of hepatotoxins, results from inhibited synthesis of the protein moiety of lipoproteins[11,12]. More specifically, Gallagher[13] has shown that, at this stage, the effect of sporidesmin in the rat resulted in decreased mitochondrial protein with decreased total activity of mitochondrial enzymes.

Probably because of a wider range of individual susceptibility, together with the highly cytotoxic action of sporidesmin, an even dose-response is difficult to obtain in a group of small animals, such as rabbits. Thus, unlike the response to a 1 mg/kg dose of sporidesmin in larger animals, the later symptoms of the diphasic clinical response[1] follow closely, or sometimes overlap, the early first-phase symptoms.

These first-phase symptoms are characterized histologically by severe hepatic necrosis and degeneration[2]. Simultaneously, mitochondrial respiration is decreased[13], followed by the changes in serum and liver triglycerides, as described here. Whatever these first-phase symptoms may be, they are transitory and reach their maximum, in the majority of animals, at about 24 h after dosing. Hepatic necrosis then subsides and cell regeneration takes place[2], whereas the liver triglyceride level declines rapidly with an equally rapid rise in serum triglyceride level (Table 1). This increase in serum triglycerides may be an 'overflow' effect of triglycerides from the liver.

The second-phase symptoms are characterized by progressive biliary cirrhosis and bile duct occlusion[2]. These symptoms are noted by gradual increases in the serum phospholipids, cholesterol and cholesterol esters. Early indications of these increases were already observed in this investigation 48 h after dosing (Table 1). In the animals which showed these increased serum lipids there were also considerable haemolysis and increases of serum bile acids and bilirubin. A rise in serum bilirubin levels has been recorded previously[14] in sheep under similar experimental conditions.

The gradual accumulation of bile acids (to be described more fully elsewhere) is of considerable interest since they may be related to the pathological and clinical changes that occur as the disease progresses[2]. Thus, the progressive bile duct occlusion and cirrhosis may be initiated by leakage of bile through injured bile channels during the early contact with sporidesmin and the subsequent process of undisciplined proliferation of biliary epithelium and fibrosis. The gradual obstruction of the normal flow of bile leads to a disturbance of the enterohepatic cycle by which bile acids, delivered to the small intestine, are largely reabsorbed and recirculated through the liver. As the result of this obstruction bile acids are retained in the liver and blood.

Pharmacologically, the bile acids are potent choleretic agents. They irritate mucous membranes, and, when injected into the circulation, they can produce severe nervous and cardiac depression and haemolysis[15]. Biochemically, bile acids are a major end-product of cholesterol metabolism, and cholesterol is probably the only precursor of bile acids. Also, their presence in the enterohepatic cycle exerts an important regulatory influence on cholesterol metabolism[16]. Thus, the feeding of bile acids, which should overload the enterohepatic cycle and depress cholesterol oxidation, causes an increase in serum cholesterol[17]. These investigators[17] also observed hyperplasia of the bile duct as a result of ingestion of lithocholic acid.

The information available at present regarding the biochemical changes induced by sporidesmin intoxication can be summarized as follows: (1) The early action of sporidesmin is similar in its effects to those of many other hepatotoxins. (2) Its effects in the rabbit (a non-

EFFECT OF NEONATAL THYMECTOMY ON THE INDUCTION OF PAPILLOMATA AND CARCINOMATA BY 3,4-BENZOPYRENE IN MICE

By GWEN GRANT, Dr. F. J. C. ROE and Dr. M. C. PIKE

Department of Experimental Pathology, Chester Beatty Research Institute, Institute of Cancer Research, Royal Cancer Hospital, London, and the Medical Research Council Statistical Research Unit, University College Hospital Medical School, London

PREVIOUS experiments in this laboratory using random-bred Schofield mice[1] and inbred *C57BL* mice[2] have shown that benign and malignant tumours arise earlier in animals whose homograft reactivity is impaired by thymectomy on the third day of life than in sham-thymectomized control mice. However, thymectomy on the third day of life has less effect on immunological function than thymectomy within 24 h of birth[3]. In some inbred strains neonatal thymectomy is associated with wasting disease if the animals are reared under conventional conditions[4,5]. However, random-bred Swiss *S* mice, thymectomized within 24 h of birth, are not affected in this way, yet show distinct impairment of immunological function as judged by their ability to form antibody in response to foreign antigens[6] and by the proportion of spleen cells capable of lysing sheep red cells when cultured with these cells using Jerne's technique[7] 4–5 days after an immunizing injection with these cells[8]. It was decided, therefore, to repeat one of the experiments previously reported in which thymectomized and sham-thymectomized mice had skin tumours induced by applications of 3,4-benzopyrene using Swiss *S* mice thymectomized during the first 24 h of life and a low weekly dose of the hydrocarbon.

Swiss *S* mice from the colony maintained at Pollards Wood Research Station were therefore thymectomized or sham-thymectomized within 24 h of birth, and 50 μg of 3,4-benzopyrene dissolved in 0·2 ml. acetone was applied to the shaved skin of the back once a week for 40 weeks beginning when the mice were approximately 6 weeks old. Papillomata and carcinomata which arose as a result of this treatment were recorded every week. Carcinomata were only so designated when they reached a diameter of 10 mm and when a biopsy taken a week after this size was first recorded showed that invasion of the panniculus carnosus muscle had occurred.

Thymectomized animals were examined after death for thymus remnants and no animals with macroscopic or microscopic fragments were included in the results. 25 thymectomized and 33 sham-thymectomized animals survived to 26 weeks of age, the time when the first papillomata appeared. The experiment was terminated 45 weeks after the initial application of benzopyrene when the survivors, 21 thymectomized and 28 sham-thymectomized mice, were 51–52 weeks old. Results are expressed in Figs. 1 and 2 in terms of the proportion of tumour-free survivors (that is, animals which have never shown the relevant tumour).

The statistical method[9] chosen to analyse this experiment is based on the hypothesis that for any animal in a given group the probability that it is tumour-free at x weeks can be written:

$$\exp\,[-b\,(x-w)^k]$$

The parameters w and k are the same for both groups (though, of course, different for papillomata and carcinomata), and the effect of the treatment is measured by the parameter b. This distribution is called the third extreme value distribution.

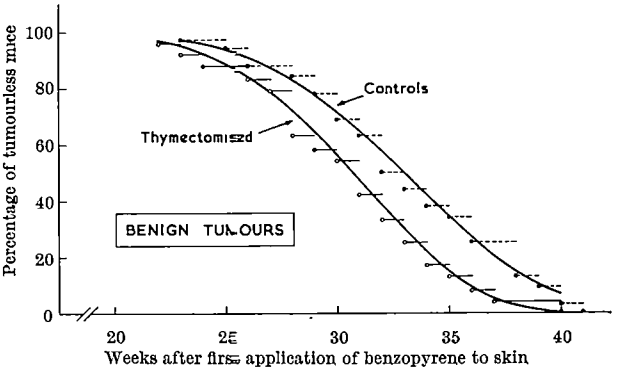

Fig 1. Percentage of tumourless mice, that is, mice without a benign tumour, at different stages of the experiment. The first appearance of a benign tumour on any animal was at 20 weeks, and (as explained in the text) what are plotted here are tumours appearing after this time. The parameters of the fitted curves stopping at 40 weeks are $k = 4\cdot34$, $w = 13\cdot97$, b (for control group) $= 1\cdot91 \times 10^{-6}$, b (for thymectomized group) $= 3\cdot35 \times 10^{-6}$, $\chi^2_1 = 3\cdot98$ for difference between b's ($P = 0\cdot05$)

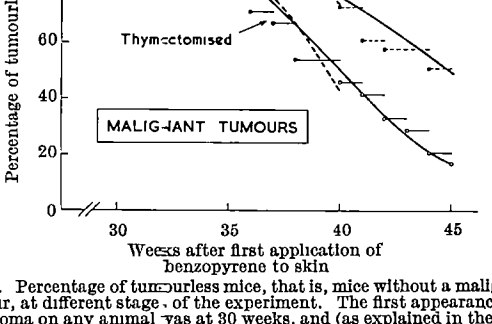

Fig. 2. Percentage of tumourless mice, that is, mice without a malignant tumour, at different stages of the experiment. The first appearance of a carcinoma on any animal was at 30 weeks, and (as explained in the text) what is plotted here are tumours appearing after this time. The parameters of the fitted curves stopping at 40 weeks are $k = 8\cdot66$, $w = 15\cdot57$, b (for control group) $= 2\cdot98 \times 10^{-13}$, b (for thymectomized group) $= 8\cdot10 \times 10^{-13}$, $\chi^2_1 = 4\cdot92$ for difference between b's ($P = 0\cdot03$)

For this distributional form there is a linear relationship between 'death'-rate (that is, the rate of getting the relevant tumour) and the logarithm of $(x-w)$; and this is precisely what is observed in many human cancers[10-12].

The parameters w, k and b are estimated by a maximum likelihood method[9] and the fits of this distributional form to the data are shown in Figs. 1 and 2. For technical statistical reasons it is convenient to consider in the figures only those animals free of tumours at the time of appearance of the first relevant tumour in any animal. The first papillomata appeared at 20 weeks and the percentage of the remaining mice without papillomata at different stages of the experiment is shown in Fig. 1. Similarly, the first carcinomata appeared at 30 weeks and the percentage of the remaining mice without carcinomata at different stages of the experiment is shown in Fig. 2. The series of short straight horizontal lines in Figs. 1 and 2 show the 'observed' proportions; for example, the papilloma results for the thymectomized group given in Fig. 1 show that 100 per cent are tumour-free from 20 weeks after the first application of benzopyrene until 22 weeks, 95·8 per cent are tumour-free from 22 weeks until 23 weeks, 91·7 per cent are tumour-free from 23 weeks until 24 weeks, 87·5 per cent are tumour-free from 24 weeks until 26 weeks, and so on. To calculate the 'observed' proportion of tumour-free survivors making allowance for intercurrent deaths an actuarial method is used[9,13].

The painting stopped at 40 weeks and, as we have previously shown[13,14] that very soon after painting ceases there is a definite break in the rate at which the first papillomata appear, we should not expect any smooth continuous curve to fit the complete experimental data. For this reason we consider here the papilloma results only up to 40 weeks (in this instance this means excluding only the final papilloma in the control group).

The fit of the suggested form of distribution is clearly good (Fig. 1) and the difference between the thymectomized and sham-thymectomized group is significant at the 5 per cent level ($\chi^2 = 3{\cdot}98$ on one degree of freedom).

The cessation of painting at 40 weeks also affected the incidence of carcinomata, so that we should not expect any smooth continuous curve to fit the complete experimental data. For this reason we consider first the results only up to 40 weeks.

The fit of the suggested form of distribution is satisfactory (broken line in Fig. 2) and the difference between the thymectomized and sham-thymectomized groups is significant at less than the 5 per cent level ($\chi^2 = 4{\cdot}92$ on one degree of freedom).

Fig. 2 also shows the third extreme value distribution fitted to the complete carcinoma data. This may be rationalized by noting that the experiment continued for only 5 weeks after painting stopped, and that the carcinomata recorded during the last five weeks were already present at 40 weeks but were too small to be counted.

If this reasoning is accepted, then the difference between the thymectomized and sham-thymectomized groups is significant at the 0·5 per cent level ($\chi^2 = 7{\cdot}94$ on one degree of freedom).

The results show that when random-bred mice are thymectomized during the first day of life so that the homograft rejection mechanism is slightly impaired benign and malignant tumours appear earlier in response to application to the skin of low doses of a chemical carcinogen. This confirms previous observations when a higher dose of benzopyrene was used and thymectomy was performed on the third instead of the first day of life.

The differences between the immunologically deficient group and the normal animals although statistically significant are not so great as to suggest that the immunological state of the host is the major factor in determining whether tumours grow or not. It may be that some tumours initiated by benzopyrene do not differ sufficiently from the host to evoke a homograft reaction against them even when the immunological competence is unimpaired. It may be that factors such as the growth-rate of the tumour allow it to progress in spite of a reaction against it, or it may be that under some conditions an animal may become specifically tolerant to a tumour which it bears.

This investigation was supported by grants from the Medical Research Council, the British Empire Cancer Campaign for Research, and the National Cancer Institute, U.S. Public Health Service.

SEPARATION OF TWO KINDS OF POLYMERASE FROM *Alcaligenes faecalis**

By DR. KATSUJI HORI, DR. HIROTA FUJIKI and PROF. YASUYUKI TAKAGI
Department of Biochemistry, Kyushu University School of Medicine, Fukuoka, Japan

SINCE the studies of Kornberg and his colleagues on the deoxyribonucleic acid polymerase of *Escherichia coli*[1], similar enzymes have been demonstrated in various sources. In general, the physical state required for the template DNA varies with the species from which the enzyme is prepared. One is represented by the *E. coli* DNA polymerase which uses double- as well as single-stranded DNA as primer; polymerases of *Bacillus subtilis*[2], sea urchin[3] and regenerating liver[4] are identified as enzymes of this type. The other is the polymerase which requires single-stranded DNA preferentially as primer; the enzymes from calf thymus[5], bacteriophage *T*2-infected *E. coli*[6] and ascites tumour[7] belong to this group. It was considered that investigations of the utilization of DNA primer by several polymerases might throw some light on the mechanism of replication.

Meanwhile, Cairns[8] has inferred from his autoradiographic investigations that the chromosome is synthesized from a fixed point and that the synthesis systematically travels along the entire length of the chromosome. Other experiments have also added support to this inference[9,10]. However, recent investigations with the *E. coli* polymerase demonstrated that this enzyme cannot synthesize two new polynucleotide chains simultaneously in the same direction from one end of a DNA template along its two strands of opposite polarity[11]. Thus, attention has recently been directed to the possibility that more than one polymerase may be involved in the replication of DNA molecules.

This article presents evidence for the presence of two separate polymerases in extracts of *Alcaligenes faecalis*. Results of our investigations reveal that one of the enzymes prefers single-stranded DNA and the other double-stranded DNA as the primer for their polymerization reaction.

* A preliminary account of this work was given at the Twelfth Symposium on Nucleic Acids, Chiba, Japan (1965).

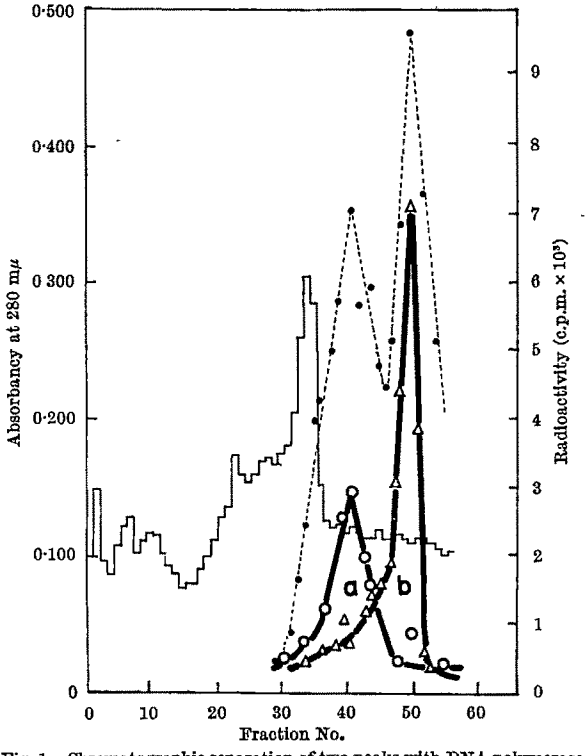

Fig. 1. Chromatographic separation of two peaks with DNA polymerase activity. A column of DEAE-cellulose (1 cm² × 27 cm) was prepared and equilibrated with 0·01 M potassium phosphate buffer, *p*H 7·0, containing 0·005 M 2-mercaptoethanol. The ammonium sulphate fraction dissolved in 10 ml. of the same phosphate buffer containing 2-mercaptoethanol was adsorbed to the column. After washing, a linear gradient of elution was applied with 0·02 M and 0·5 M sodium chloride, as limiting concentrations. Sodium chloride was dissolved in 0·01 M potassium phosphate buffer, *p*H 7·0, containing 0·005 M 2-mercaptoethanol and 150 ml. of each solution were used. The flow rate was 10 ml. per h, and 3-ml. fractions were collected. The activity of the eluted fractions was assayed by the standard assay system, with native (—△—), denatured (—○—), and 'activated' calf thymus DNA (- - - ● - - -) as primer, respectively. Absorbancy of each fraction at 260 mμ is also shown (———)

The strain used in these experiments was *Alcaligenes faecalis LB*, which was kindly provided by Dr. K. G. Lark, of Kansas State University. Fractions with polymerase activity were obtained from a frozen cell paste following a procedure of sonic disintegration, streptomycin precipitation, protamine precipitation, ammonium sulphate fractionation and DEAE-cellulose chromatography. Details of the preparation will be described in a subsequent publication[12]. In the routine assay of DNA polymerase activity, the conversion of tritiated thymidine triphosphate (^{3}H-TTP) into an acid-insoluble product was measured. The reaction mixture (150 μl.) contained 5 μg of DNA primer, 10 μmoles of glycine buffer, *p*H 9·0, 1 μmole of magnesium chloride, 5 mμmoles each of dATP, dGTP and dCTP, 3 mμmoles of ^{3}H-TTP ($1·6 \times 10^7$ c.p.m. per μmole), and various quantities of enzyme preparation. After incubation for 30 min at 37° C, the reaction was stopped by the addition of 0·3 ml. of cold 1 N perchloric acid and the acid-insoluble fraction was isolated by centrifugation as described before[13]. Radioactivity measurements were made in a window-less gas flow counter ('*Aloka*'). A unit of enzyme activity was defined as described by Richardson *et al.*[14]. Protein was determined by the method of Lowry *et al.*[15]. Tritiated TTP was prepared by enzymatic phosphorylation of ^{3}H-thymidine (Schwarz BioResearch, Inc.) by a crude extract of calf thymus and purified on a 'Dowex-1' (Cl^-) column. Unlabelled deoxyribonucleoside triphosphates were purchased from the California Corporation for Biochemical Research. Various DNA primers were isolated as follows: calf thymus DNA according to Kay, Simmons and Dounce[16]; bacterial DNA by the method of Marmur[17]; *T2* DNA as described by Mandell and Hershey[18]. 'Activated' calf thymus DNA was obtained by exposing the DNA

Table 1. REQUIREMENTS FOR REACTION

System	^{3}H-dTMP incorporated (μμmoles) Peak fraction *a*	Peak fraction *b*
Complete	665	260
Minus DNA	0	0
Minus magnesium chloride	0	<1
Minus dATP	34	17
Minus dGTP	36	13
Minus dATP and dGTP	28	7
Minus dATP, dGTP and dCTP	27	4

The complete system for the reactions is described in the text. For columns 1 and 2, respectively, 5 μg of heat-denatured DNA and 4·8 units of fraction *a* and 5 μg of native DNA and 0·7 unit of fraction *b* were used.

to crystalline pancreatic DNase (Worthington Biochemical Corporation) according to the method of Aposhian and Kornberg[6]. Heat-denatured DNA samples were prepared by maintaining a solution of DNA at 100° C for 10 min and then immediately cooling it in an ice water bath.

When fractions eluted from DEAE-cellulose column were assayed with 'activated' calf thymus DNA as the primer, polymerase activity was distributed in two separate peaks (peaks *a* and *b*) on the chromatogram as shown in Fig. 1. Investigations of the requirements for the reaction catalysed by these two peaks revealed fundamental similarities to the *E. coli* polymerase. The omission of one, two or three of the four deoxyribonucleoside triphosphates resulted in a marked reduction of the reaction. The presence of a DNA primer and a magnesium ion was essential for the reactions, as can be seen from Table 1. However, difference in the effectiveness of the primer was observed for two peaks. One of the peak fractions (*a*) eluted with a low concentration of sodium chloride exhibited an activity about ten times greater with heat-denatured DNA as primer than with native DNA. Also the single-stranded DNA from φ*X*174 phage was an effective primer without heating. On the other hand, the other peak fraction (*b*), eluted later with higher concentration of sodium chloride, was far more active with native DNA than with heat-denatured DNA (Table 2). Additional evidence for the dissimilarity in primer requirement was obtained from experiments in which the effects of heat-denaturation of native DNA on the priming activity were investigated with various DNA samples, in which were included calf thymus, *Escherichia coli*, *Alcaligenes faecalis*, *Pseudomonas aeruginosa*, *Aerobacter aerogenes* and bacteriophage *T2* (Fig. 2). With fraction *a*, priming activity of native DNA was dramatically increased by heating for 10 min at a temperature higher than 75° C, followed by quick cooling. Conversely, with fraction *b*, priming activity of native DNA was reduced in proportion to the grade of its denaturation, when heated at a temperature higher than 75° C, and DNA heated at 100° C had activity corresponding to 10–20 per

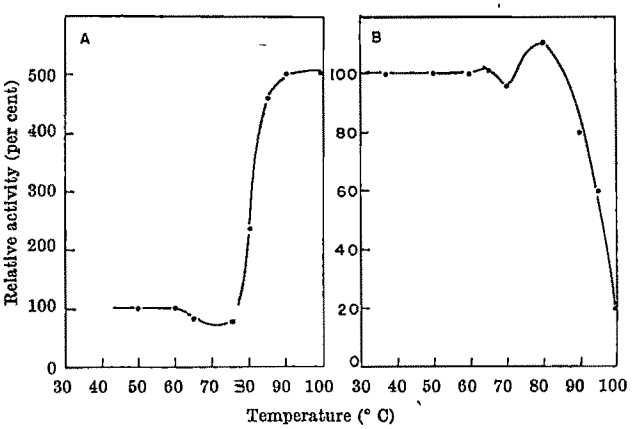

Fig. 2. The effects of heat-denaturation of DNA on the priming activity. A solution of DNA (100 μg per ml. in 0·01 M potassium phosphate buffer, *p*H 7·0, and 0·15 M sodium chloride) was kept at various temperatures for 10 min and then immediately cooled in an ice-water bath. Priming activity of these heated DNA samples was assayed in the standard incubation mixture described in the text. For experiment *A*, *P. aeruginosa* DNA and 1·1 units of peak fraction *a*; and for *B*, calf thymus DNA and 0·5 unit of peak fraction *b* were used, respectively

Table 2. ACTIVITIES OF VARIOUS DNA PRIMERS FOR TWO POLYMERASE PEAKS

Primer	Acid-precipitable radioactivity after incubation (c.p.m.) Peak fraction *a*	Peak fraction *b*
Calf thymus DNA, native	793	7,136
Calf thymus DNA, heated	5,814	916
Calf thymus DNA, 'activated'	9,217	9,676

Primer effectiveness for fractions *a* and *b* was studied by comparing acid-precipitable radioactivity after 30 min of incubation with different samples of calf thymus DNA as primer under the standard experimental conditions described in the text. The enzyme used was 0·8 unit of fraction *a* or 1·8 units of fraction *b*.

cent of that obtained with non-treated native DNA. The reduced level (Fig. 2*A*) or the augmented level (Fig. 2*B*) of priming activity observed at about 70° C may be due to the transition of a single-stranded part in native molecule of DNA to double-stranded structure. In the next experiments the two fractions were compared for affinity to native and heat-denatured DNAs, and for maximal velocity of the reaction with both primers. The results were plotted in Fig. 3, according to the method of Lineweaver and Burk[18]. Fraction *a* had a higher affinity for denatured DNA than for native DNA, whereas with fraction *b* the opposite was observed. Thus, the polymerase activities exhibited by fractions *a* and *b* were distinct and separable.

It could have been assumed that the polymerization fraction *b* with native DNA as primer was due to combined action of a nuclease persisting in the fraction and supplying native DNA to an 'activated' template, and a polymerase active for denatured DNA as primer—the same enzyme as that eluted in the fraction *b* fractions. However, there are several points against this. First, treatment of a native DNA sample with fraction *b* for various periods at 37° C, in the absence of the four deoxyribonucleoside triphosphates, did not improve its priming capacity (series 1 of Table 3). The primer effectiveness of the DNA thus treated was not elevated even when heated for 10 min at 100° C and quickly cooled after pre-incubation, and there was only a marked decrease due to heat-denaturation (series 2 of Table 3). Secondly, when two fractions were mixed in various proportions, polymerase activity with heated or unheated DNA as primer was closely equal to the sum of the activities assayed separately with each peak and neither stimulation nor inhibition was observed (Table 4). Finally, when a mixture of the two fractions was chromatographed on hydroxyapatite, there were again two discrete peaks of polymerase activity, one primed by single-stranded and the other by double-stranded DNA (Fig. 4). Therefore, it was suggested that different entities may be responsible for two polymerase activities.

One possibility is that artificial modification in the course of purification, for example, partial destruction of the conformation, attachment of unusual materials such

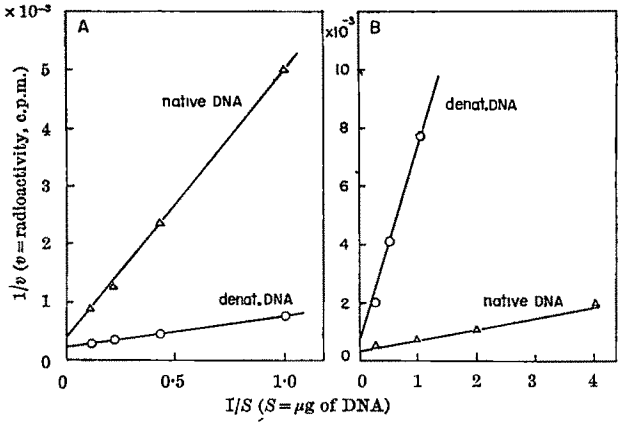

Fig. 3. The effects of primer concentration on the reaction rate. The standard assay conditions were used, except that the concentration of native and denatured DNAs added as primer was varied. The enzyme was 4 units of fraction *a*, and 0·5 unit of fraction *b* for experiments *A* and *B*, respectively

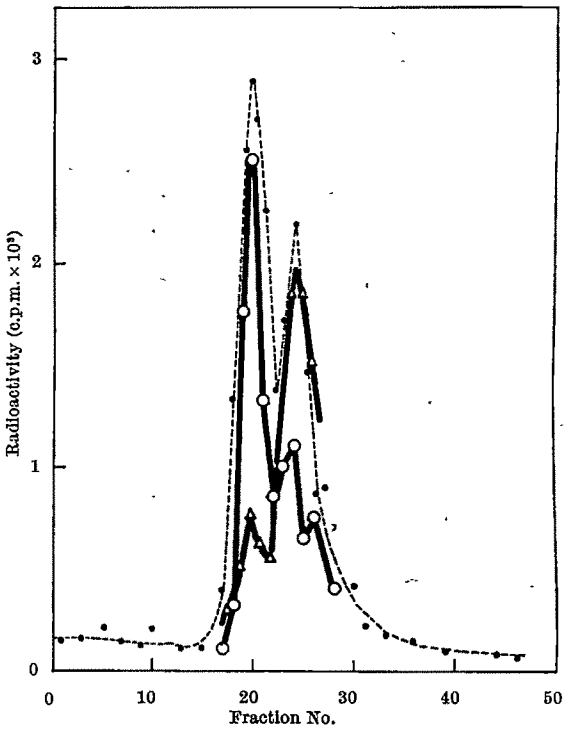

Fig. 4. Chromatography of a mixture of fractions *a* and *b* on hydroxylapatite. A column of hydroxylapatite (1 cm² × 7 cm) was prepared and washed with 0·001 M potassium phosphate buffer, *p*H 7·0, containing 0·005 2-mercaptoethanol. Two polymerase peak fractions from DEAE-cellulose chromatogram were combined (18 ml.), applied to the column, and elution was achieved with a linear gradient of potassium phosphate buffer ranging from 0·02 to 0·3 M at *p*H 7·0. The buffers contained 0·005 M 2-mercaptoethanol and 80 ml. of each buffer were used; fractions of 3 ml. were collected every 20 min and assayed for polymerase activity as described in the text, with native (—△—), denatured (—○—), and 'activated' calf thymus DNA (- - - ● - - -) as primer, respectively

as streptomycin or protamine, or interaction with naturally occurring components such as proteins or nucleic acids persisting in the fraction, is responsible for the heterogeneous character of polymerase activity on the chromatography. Both polymerase activities, however, were always detected, even when the streptomycin fraction was exposed to digestion with pancreatic DNase in

Table 3. EFFECTS OF PRE-INCUBATION OF NATIVE DNA WITH PEAK FRACTIONS *a* ON THE PRIMING ACTIVITY

Exp. series	Pre-incubation (min)	Acid-precipitable radioactivity after incubation (c.p.m.)
1	60	2,060
	30	2,421
	20	3,002
	10	3,064
	5	2,754
	0	3,009
2	60	411
	30	506
	20	786
	10	530
	5	587
	0	604

Five μg of calf thymus native DNA was incubated at 37° C for various intervals described in the table with 10 μmoles of glycine buffer, *p*H 9·5, 1 μmole of magnesium chloride and 0·2 unit of fraction *b* in a total volume of 80 μl. Then, in series 1, four deoxyribonucleoside triphosphates were immediately added to the reaction mixture, and priming activity of DNA thus treated was measured by counting the acid-precipitable radioactivity after a 30-min incubation at 37° C. In series 2, the reaction mixture after pre-incubation was heated for 10 min at 100° C and quickly cooled, then subjected to the assay for priming activity by the addition of four deoxyribonucleoside triphosphates and 0·2 unit of fraction *b*.

Table 4. POLYMERASE ACTIVITY OF THE MIXTURE OF TWO PEAK FRACTIONS *a* AND *b*

Enzyme (μl.) Peak *a*	Peak *b*	Acid-precipitable radioactivity after incubation (c.p.m.) Native DNA	Heat-denatured DNA
30	0	541	2,860
0	30	5,809	845
10	30	5,987	1,872
30	10	2,540	3,250
30	30	6,520	3,716

The standard assay system was used with indicated volume of fractions *a* (36 units per ml.) and *b* (20 units per ml.) added as the enzyme.

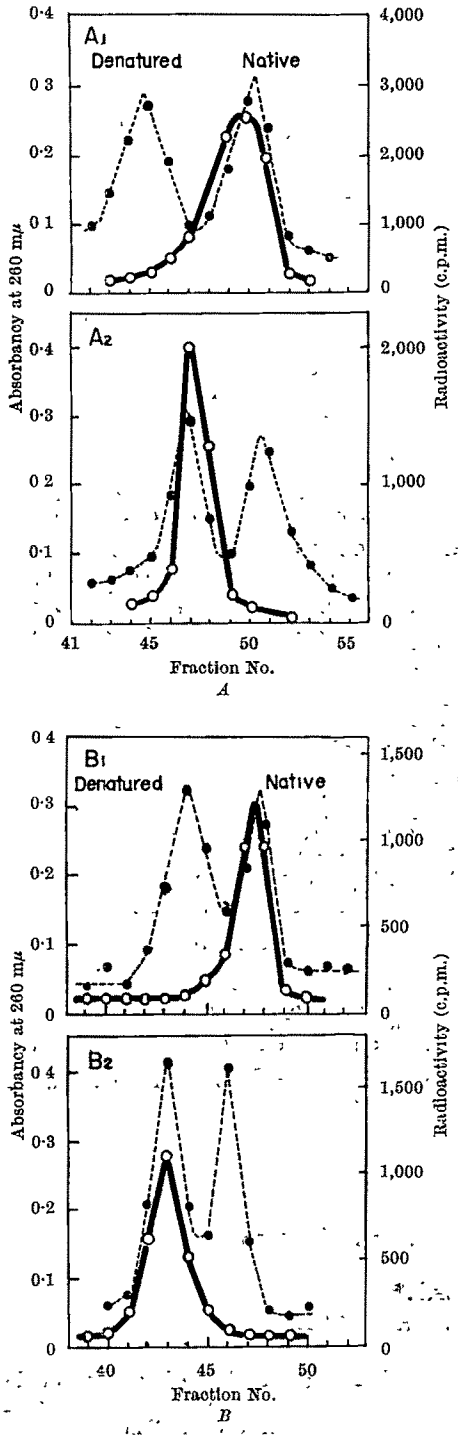

Fig. 5. 'Geon' zone electropherograms of reaction product. *A*, The incubation mixture (750 μl.) contained 22 μg of heat-denatured calf thymus DNA, 50 μmoles of glycine buffer, *p*H 9·0, 10 μmoles of magnesium chloride, 15 mμmoles each of dATP, dGTP, dCTP and ^{3}H-dTTP, and 20 units of the *S*-polymerase. After 3 h of incubation at 37° C, the reaction mixture was deproteinized by phenol, dialysed against 500 ml. of 0·15 M sodium chloride-0·01 M potassium phosphate buffer, *p*H 7·0, for 12 h at 4° C. Tritium-labelled product thus obtained was divided into two portions: one was heated for 10 min at 100° C and cooled quickly, and the other left untreated. To both portions were added 250 μg each of unlabelled native and heat-denatured DNA as references and 0·7 ml. of 0·03 M citrate buffer, *p*H 6·5, and electrophoresis was carried out on unheated product (A_1) and heat-denatured product (A_2) for 16 h at 4° C as described by Matsubara and Takagi (ref. 20). *B*, The incubation mixture (3·0 ml.) contained 100 μg of native calf thymus DNA, 200 μmoles of glycine buffer, *p*H 9·0, 40 μmoles of magnesium chloride, 100 mμmoles each of dATP, dGTP, dCTP and ^{3}H-dTTP, and 10 units of the purified *D*-polymerase. After incubation for 5 h, the reaction mixture was deproteinized by phenol and then dialysed against 500 ml. of 0·15 M sodium chloride-0·01 M potassium phosphate buffer, *p*H 7·0, for 12 h at 4° C. The other experimental conditions were the same as described in *A*. Mobility of native and denatured DNAs added as references was indicated by absorbancy at 260 mμ of each fraction (- - - ● - - -)

order to remove nucleic acids more extensively, and followed immediately by chromatography on a DEAE-cellulose column without protamine treatment and ammonium sulphate fractionation. The same results were obtained when the streptomycin non-precipitable fraction was applied to a DEAE-cellulose column. Therefore, it seems unlikely that the two polymerase activities are associated with a single protein. The fraction *a* enzyme will be tentatively referred to as polymerase primed by single-stranded DNA (*S*-polymerase), and the fraction *b* enzyme by double-stranded DNA (*D*-polymerase), respectively.

Three experiments were carried out in order to determine the structure of the reaction product. When the amount of acid-precipitable product, synthesized with *S*-polymerase and with denatured DNA as primer, had attained approximately 50 per cent of the amount of primer added, the product was subjected to the following procedures: (1) when tested by zone electrophoresis with 'Geon'[20], the reaction product was found in a peak with mobility similar to that of the double-stranded DNA, added as reference, whereas the same product after heat-denaturation represented a peak of identical mobility with that of DNA in single-stranded structure (Fig. 5*A*); (2) another aliquot of the product was applied on a methylated serum albumin column (1 × 3 cm), then eluted with sodium chloride using stepwise increase of the concentration[21]; the product was eluted quantitatively with 0·7 M sodium chloride, while the product after heat-treatment was scarcely eluted by sodium chloride up to 1 M; (3) the product was not hydrolysed by the action of exonuclease I of *E. coli* purified as described by Lehman[22]—an enzyme known to have a high specificity toward single-stranded DNA—whereas, after previously heated for 10 min at 100° C and quickly cooled, it was gradually degraded by the enzyme, as shown in Fig. 6. Similar results were also obtained with the product of *D*-polymerase reaction (Fig. 5*B*). Then it was found that both polymerases give product in a single-stranded structure, which is easily converted to single-stranded form by heating and rapid cooling.

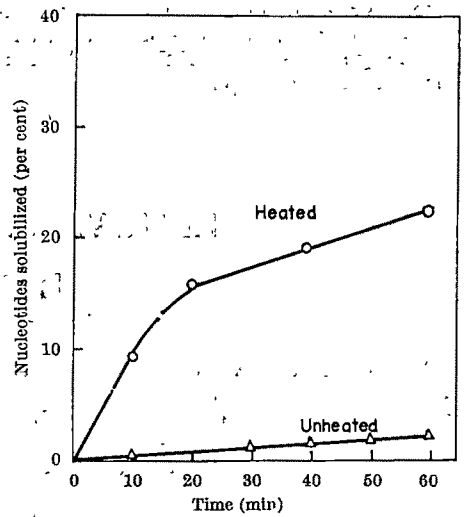

Fig. 6. Enzymatic digestion of reaction product. Tritium-labelled reaction product by *S*-polymerase was prepared according to the procedures described for Fig. 5. The incubation mixture (1·0 ml.) contained 250 μg of heat-denatured calf thymus DNA, 10 μg of tritium-labelled reaction product heated or unheated, 25 μmoles of glycine buffer, *p*H 9·5, 5 μmoles of magnesium chloride, and 25 μg of *E. coli* exonuclease I. After incubation at 37° C, aliquots were taken at intervals and the radioactivity rendered acid-soluble was measured

From the results described in this article, it would seem that *Alcaligenes faecalis* contains two separate polymerases; however, it is possible that the enzyme exists in the cell in an aggregate form but that under the conditions used for the extraction or purification it has become partly separated into sub-units resulting in dif-

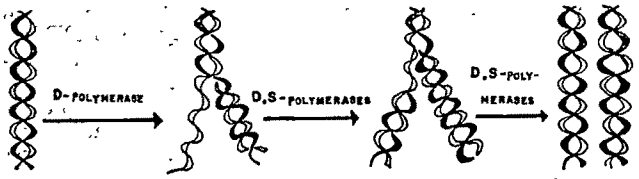

Fig. 7. Schematic mechanism of DNA replication

ferent chromatographic behaviour and different primer requirements.

There are several interpretations of the function of the two different polymerases present in one source. In order to explain the replication of chromosome in the cell as it is at present known, it is necessary to assume that two kinds of reaction proceed simultaneously from one end of a DNA template, along its two strands of opposite polarity. One is the interaction of the 3′-hydroxyl group of a deoxyribonucleoside triphosphate with the 5′-phosphate group of the terminal nucleotide of DNA strand (type I), and the other is the attack of the 5′-phosphate group of a deoxyribonucleoside triphosphate on the terminal 3′-hydroxyl group of DNA chain (type II). The *E. coli* polymerase is known to initiate its 'replicating' reaction from the 3′-hydroxyl end of the template strand, according to the mechanism of type II (ref. 11), but as yet the enzyme responsible for the other type of reaction (type I) has not been found in Nature. Another peculiarity is that the product of DNA polymerase from *E. coli* is unlike native DNA in two respects: (i) from electron microscope studies it seems to be a multi-branched form; (ii) it renatures fully after heating and quick cooling[23]. These may explain the failure to replicate biologically active DNA. Thus there is no enzymatic mechanism available to explain the replication process of chromosomes in the cell, and some doubts have been expressed as to whether the DNA polymerases we have are "only repair enzyme". At present, it is not possible to say whether or not these enzymes are involved in DNA replication or not, but there are two possibilities if this is so: (1) the enzymes are responsible for initiating two different types of reaction in the cell, but only one reaction in *in vitro* conditions; (2) the cell is provided with another enzyme for the type I reaction. Efforts are being made in many laboratories to explore polymerase activity, different from these polymerases, with regard to the direction of 'replication'. However, if the two distinct polymerases referred to in this article are not both repair enzymes, then it is possible that our observations indicate that polymerases—essentially related to DNA replication—are different in their primer requirement as well as in the type of reaction already mentioned. Furthermore, this suggestion fortifies a plausible hypothesis for DNA replication in the cell as indicated in Fig. 7. The *D*-polymerase may initiate the reproduction from one end of a DNA template along one of its two strands, leaving another strand free which will sequentially serve as a template for *S*-polymerase. Thus, the replication may continue until the two daughter molecules are completely formed. We are at present investigating this hypothesis.

This investigation was supported by a U.S. Public Health Service grant.

HEARTWOOD FORMATION IN TREES

By DR. PETER RUDMAN*
Astbury Department of Biophysics, University of Leeds

DESPITE the fact that wood has been used by man for countless ages, and that countries throughout the world are devoting an increasing amount of time to the planting and cultivation of trees, one of their most important features still is not understood, namely why trees form heartwood.

Only two basically different hypotheses concerning heartwood formation have been put forward, the first involving moisture–air relationships in the cells, the second fungal infestation. The former, which has received by far the greater support, has a number of variants, but neither hypothesis has been used or can be used to explain genetic and environmental differences in heartwood formation. It is the purpose of this article to present a third hypothesis and to illustrate its value by offering explanations for some of these genetic and environmental differences.

* Permanent address: Division of Forest Products, C.S.I.R.O., South Melbourne, Australia.

Before embarking on this discussion of heartwood formation, I consider that a few introductory remarks on heartwood would be in order. There is no adequate definition of heartwood, but it is usually considered to be the wood within a tree which is distinct from sapwood, for example, is of a different colour, is usually of a lower moisture content, may contain a higher extractive content, may be of higher durability, may be tylosed, and in which the cells including ray parenchyma are dead.

In the first hypothesis to be put forward on heartwood formation, Priestley[1] contended that heartwood resulted from the accumulation of air in the closed vessel systems, and the resultant effect on permanent water content brought about secondary changes in the living parenchyma cells. It has been pointed out[2] that this view is supported by the relatively constant thickness of sapwood within a species and sometimes a genus; however, it was considered necessary to explain why the length of life of sapwood ray cells of various species differs so greatly

and also why the age at which sapwood becomes heartwood in roots, branches and stems is so different. A variant of this hypothesis is that of Zycha[3], who believed that the water requirements of the crown reduced the inner sapwood moisture content, so causing air to be drawn in through dead or broken limbs, and it has been suggested[4] that formation of 'false heartwood' brought about by artificial means supports this hypothesis—as does the absence of fungal infection[5].

In the second hypothesis, Münch[6], Büsgen and Münch[7], Jacquiot[8] and Chattaway[9] believed that fungal infection initiated the transformation. This hypothesis has not received wide support, and one of the major criticisms is that it is frequently not possible to isolate fungi from the appropriate wood. It has been suggested[2] that if this were the correct hypothesis it would have to be used to explain why normal heartwood is usually symmetrical in shape and position, and also why concentric rings of included sapwood are found.

The third, and new, hypothesis, which I shall present here, depends on the fact that: (1) Water requirements of the crown may reduce the moisture content of the inner parts of the tree at certain periods[8,10,11]. (2) The food economy of the young tree, if considered in the terms of Kramer and Kozlowski[12,13], which involves income (food manufactured by photosynthesis), expenditure (assimilation and respiration) and balance (food accumulated and used as a metabolic substrate at a later date), is efficient, such that an over-production of storage food does not occur. (3) Food economy efficiency decreases with age, so that the reserve food and the by-products of increased respiration are not completely re-utilized. (4) Hydrolysis of starch to sugar will occur as a result of water deficit[14,15]. (5) Redistribution of soluble carbohydrate will occur between living cells in both centrifugal and centripetal directions. (6) Xylem cell walls, even in dead sapwood cells, behave as semi-permeable membranes and will allow centripetal and centrifugal flow of water and certain solutes[16,17]. (7) Respiration will continue in inner ray parenchyma (because of the presence of carbohydrate and related compounds), even under conditions of reduced moisture content. Such conditions should favour reactions which increase the gas pressure (though the oxygen content may fall and the carbon dioxide content rise).

In the rapidly growing young tree little food is reserved, but after a few years the tree produces greater amounts of reserve foods. When, for example, the reserve starch is being reabsorbed by hydrolysis to sugar the reaction will proceed if the reaction product(s) is removed. If it is not removed, then equilibrium will be attained and the reaction will cease; however, the product should move in both a centrifugal and a centripetal direction in an attempt to reach equilibrium. Because large amounts of soluble reserve food are utilized at these times in those parts of the tree which are actively growing, we tend to consider that only centrifugal flow occurs and we have overlooked the fact that there is a competing centripetal flow in which the initial driving force is the need of the starving ray parenchyma and the normal diffusion laws. The rate of centripetal flow will clearly be dependent on the rate of centrifugal flow, and the absolute amount of material will vary according to the availability of soluble reserve food. It should be pointed out that centripetal flow of solute may occur concurrently with a centrifugal flow of water if the concentration (but not the absolute amount) in the inner sapwood is lower than in the outer sapwood. Centripetal flow of carbohydrate should cease if, and when, equilibrium is attained. But if the soluble carbohydrate is transformed into a further substance which for convenience we shall call an extractive, by an irreversible reaction such as may occur in a ray parenchyma cell, then equilibrium will not be attained and centripetal flow of the carbohydrate will continue—just as centrifugal flow continues. For similar reasons, centripetal flow of the reaction products will tend to continue. For convenience so far, only one food reserve material or extractive has been considered, but it will be quite clear that a series of extractives could be involved. For example, in an angiosperm it could be starch changing to a carbohydrate *A* changing in turn to an extractive *B*, which is again transformed to *C*. Ultimately an extractive *E* is produced which has a relatively low solubility in aqueous solution ('sap') and so is precipitated. Thus we have the beginning of heartwood formation, since further centripetal flow can now take place to maintain equilibrium. It is only by such centripetal flow that we can explain why heartwood may have a higher extractive content than the corresponding sapwood, and the increase in extractives of the heartwood type on the cambial side of insect holes in sapwood and their reduced concentration on the pith side.

It will be noted that it has not been necessary to consider the detailed mechanisms involved in cell transport and death, and the reader is referred to Frey-Wyssling and Bosshard[18] and Nečesany[19] for an explanation of cytological changes which occur in sapwood–heartwood transformation.

The position at which precipitation is occurring, and which we may term the heartwood–sapwood boundary, will be moving away from the pith if the moisture content falls during the year. Thus the extractive content of the heartwood at a specific position should be related to the tree's efficiency in producing cellular materials and its ability to re-use its own food reserves. It should be pointed out that if precipitation did not occur, extractives may also tend to move back towards the sapwood to maintain equilibrium, with the result that extractive contents would not vary radially.

This hypothesis offers satisfactory explanations for a number of phenomena, thus overcoming major obstacles to its acceptance in a general sense; some of these will now be discussed.

A species which is not efficient will produce heartwood when quite young, and as the tree increases in age, so its efficiency will decrease with the result that its sapwood thickness will decrease and its heartwood extractive content increase. A species which is efficient will not produce heartwood when it is young, and in fact may never produce normal heartwood. (The so-called pathological heartwood may develop at a later stage because of fungal attack.) In between the two limits we will have species with wide sapwoods and which produce heartwood late in life.

So far it has been suggested that a combination of a tree's inability to obtain sufficient water (and probably inorganic constituents) and the fall in efficiency governs the time of heartwood formation and subsequent sapwood thickness. If the change in efficiency is rapid, then this will contribute to an early increase in heartwood extractive content.

Let us examine its explanation of the fact that within a species trees which have grown slowly in general have a higher heartwood extractive content than trees which have grown quickly. It is known, for example, that starch reserves rise in dry weather in the northern hemisphere deciduous trees, and further proof of this association comes from the finding[20] that some heartwood evergreens (*Eucalyptus* species) in Australia exhibit two general rises and falls in starch content in each year which are associated with two periods of moisture shortage and slow growth. This starch, if inadequately re-absorbed, is free to produce heartwood extractives, so an association between moisture stress, slow growth and high extractive content is evident. The converse of this basic reasoning explains why trees which have grown quickly are found to contain low extractive contents; indeed the high growth rate in the very young tree is also associated with a low extractive content and it would appear that the faster the tree grows the fewer 'by-products' it produces.

It has been reported[21] that good dominant *Pseudotsuga menziesii* trees have a wider sapwood than the average tree, that the sapwood is wider on good sites for the top and middle of the stem, and that the sapwood is thickest at the base of the stem and least in the middle of the stem. Also that *Fraxinus excelsior* has a higher wood moisture content and later heartwood formation on moist sites and in milder regions, in fact is a facultative heartwood producer whereas in continental regions it is an obligate heartwood producer[22]. Conditions which favour high growth rate include an adequate rainfall, and then the demand for water from the wood nearest to the pith is low; thus there could be a low centrifugal migration of water in the stem, which would cause a later than usual precipitation of extractives, hence a wider sapwood. On the basis that the lower part of the stem is closest to the source of water (the roots) one would expect that the water stress would be low and thus the sapwood would be wide, whereas higher up the stem it would be narrower owing to the water stress being greater. It is tempting to suggest that the upper stem sapwood thickness would be greater because of its proximity to the crown, but this would be mere wishful thinking.

Related to these explanations is an explanation for the formation of heartwood at differing ages in roots and stems. For example, *Robinia pseudoacacia*, seldom contains more than a few annual rings which are free from tyloses, and is known for its narrow sapwood, whereas tyloses and heartwood formation are absent in even the twentieth ring in the roots[7].

On the basis of the present hypothesis, formation of a fairly symmetrical heartwood is not unexpected, since the branches are situated reasonably symmetrically around the upper stem and so the demands of the crown for water are transmitted fairly evenly around the stem perimeter. Likewise the positioning of the roots ensures a fairly even supply of water to the base of the stem. Nevertheless, it is known that small moisture content variations do occur around the stems, and minor unevennesses in heartwood formation are known. Whether these correlate should prove an interesting study.

It has been pointed out[2] that the heartwood periphery of a stem containing tension wood shows no relationship with the growth rings or age of the living cells. Also, any hypothesis should be able to explain why the heartwood extractive content of tension wood is considerably lower than that of the opposite wood. Tension wood is produced in response to an external stimulus and the tree is able to control its response.

Tension wood is wood of high growth rate, and on the basis of the previous assumption of increased efficiency being associated with high growth rate, then the extractive content of tension heartwood would be expected to be low. On the opposite side of the tree, though there is a reduction in growth rate, there is no marked change in the availability of water as may be the case in suppressed trees, so there is no need markedly to reduce the sapwood thickness.

The formation of concentric rings of included sapwood (target rings) must now be considered. This is clearly the result of variations in the amounts of reserve food available for centripetal flow. When the amount available is low, then a heartwood is produced which is so low in extractives as to appear to be sapwood. On the return of normal conditions, the centripetal flow is resumed, and proceeds to a position which is determined, in effect, by the availability of moisture within the tree, precipitation occurring when saturated solutions are obtained. The zones of low extractive content that stand out, usually as lighter coloured, including sapwood on the pith side of insect holes or scars, are also heartwood to which normal centripetal flow of extractives has been stopped. However, the sapwood side of the injury may also contain an area of low extractive content according to the rate of moisture loss into and through the hole. Next to this zone will be a zone of high extractive content, since this contains those extractives which were originally centripetally flowing to the included sapwood zone. Examination of such zones reveals the normal heartwood constituents, indicating that premature desiccation produced results comparable with the normal heartwood process.

Similar reasoning may be used to explain the failure to increase the proportion of obvious heartwood in oak and larch by girdling[23] because clearly the centripetal flow of extractives had been interrupted.

On the basis of the previous discussions it will be seen that species which tend to be referred to as sapwood species must no longer be considered to be anomalous, whether there is or is not a step-wise change in extractive content at some position across the radius of the stem.

It should be pointed out that in the sapwoods of hardwood species, the initially formed extractives are water soluble and frequently polysaccharides[24]. Any modification of these, particularly aromatization, decreases their water solubility. It seems understandable, therefore, that the heartwood extractives of many hardwoods include aromatic substances. Nevertheless, non-aromatic compounds, such as terpenes, which are relatively insoluble in water, will produce the same effect.

There are numerous other examples where this hypothesis can be successfully applied, and readers will be able to try for themselves a number of their own observations. Nevertheless, a cautionary remark may prove helpful and avoid the hypothesis being discredited on limited evidence. It would seem worth while to illustrate this by an example of the failure of the hypothesis to predict what has been reported, but which I believe does not discredit the hypothesis.

Pinus radiata grown in New Zealand has been investigated[25] and the conclusion drawn that physiological drought retards heartwood formation, but that with a deep root, adequate rainfall and low drying conditions, heartwood formation is at a maximum (compare this with the results for *Pseudotsuga menziesii*), though again dominant trees contained a wider sapwood than suppressed trees. Immediately, this unexpected result suggests that factors other than the availability of moisture are of some importance; for example, to what extent are mineral deficiencies involved in controlling what has been referred to as 'true efficiency'.

It is not my intention to imply that this hypothesis is perfect or complete; rather it is intended that it should stimulate thought and so provoke biochemists, botanists and foresters into planning further research into this most intriguing facet of Nature.

ASTROPHYSICS

A Search for Variations in the Flux of the Quasi-stellar Source *CTA* 102

THE source *CTA* 102 has evoked considerable interest following Sholomitsky's[1] announcement that the flux at 32·5 cm varied 25 per cent, with a period of about 100 days. Caswell and Wills[2], however, could find no evidence for variations at 1·7 m in their observations made during the same period. The determination by Schmidt[3] of a red shift for *CTA* 102 $\Delta\lambda/\lambda = 1{\cdot}037$, placing the object at a distance of about 3,000 Mpc, contradicts Sholomitsky's estimate of $\sim$ 2 Mpc, based on angular size and light travel time. Maltby and Moffet[4] have since examined results of measurements made by the California Institute of Technology at 31·4 cm, and for the period 1959·7–1961·7 found no significant variation, and concluded that Sholomitsky's result is probably in error.

Rees and Sciama[5] have attempted to reconcile Sholomitsky's result with the 178 Mc/s and red-shift data. They assume synchrotron self-absorption to account for the lack of variation at 178 Mc/s, and postulate a rather improbable geometry to resolve the difficulty of light travel time. On the basis of this model they predicted a variable component with a 25 per cent peak amplitude, for frequencies greater than 1,000 Mc/s.

We have undertaken measurements spanning a period of 75 days, from September 16 to November 29, 1965, to detect possible variations in the flux density of *CTA* 102 at 13 cm (2,295 Mc/s). Measurements were made with an 85-ft. polar mounted antenna at the National Aeronautics and Space Administration Deep Space Station at Hartebeesthoek, near Johannesburg, South Africa. A right-hand circularly polarized feed was used. The radiometer uses a travelling-wave maser, and peak-to-peak fluctuations are of the order of 1 flux unit, with a post-detection integration time of 5 sec. Full details of the equipment will appear elsewhere[6].

Observations were made at 2–4 day intervals. The sources 3*C*33 (S = 8 F.U.) and 3*C*353 (S = 38 F.U.) were chosen as control sources to check stability of the flux scale, since these have both been identified with *D* galaxies[7], and thus would not be expected to vary. From weekly averages for 3*C*33, the long-term stability of the flux scale, referred to an argon standard, was found to be constant to better than ± 1 per cent over the observing period. Day to day stability was checked for 12 days from September 16 to October 30 from observations of 3*C*33 and 3*C*353. Peak deviation from the average was ± 1·5 per cent with a median deviation of ± 1 per cent.

The results for *CTA* 102 are shown in Fig. 1. Each point is the average of nine measurements and the bars indicate the standard deviation for each set of measurements. The data indicate no evidence for the 100 day, 25 per cent variation. Of twenty-nine values, twenty-two are within ± 2·5 per cent of the mean, six between ± (2·5–5) per cent, and only one point deviates by 6 per cent. This scatter is no greater than would be expected from measurement inaccuracies, and there do not appear to be any day to day variations greater than 5 per cent.

Fig. 2 shows averages of flux density over approximately weekly periods, each point being the mean of twenty-seven observations. Peak-to-peak scatter about the mean is 6 per cent. Also shown is the expected variation, from extrapolation of Sholomitsky's result, and assuming the model proposed by Rees and Sciama. We conclude that any variation with a period of the order of 100 days has a peak-to-peak amplitude < 6 per cent, and hence the flux of such a variable component is < 0·3 F.U. If the source is still variable at 32·5 cm, then the spectral index of the variable component must be greater than 2, between λ = 32·5 and 13 cm.

Suggested Mechanism for the Anomalous Excitation of OH Microwave Emissions from H-II Regions

STRONG microwave emission lines at 18 cm have recently been reported from a number of sources[1–3], the frequencies being close to those of the hyperfine components of the Λ-doublet of the ground state ($X\ ^2\Pi_{3/2}$, J = 3/2) as measured in the laboratory[4]. Λ-doubling is due to coupling between the rotation of the nuclei and the orbital rotation of the electrons, which has a quantum number Λ = 1 in the Π state. The energies differ slightly

according to the relative orientation of the two angular momenta. Coupling with the nuclear spin of the proton leads to further hyperfine splitting (Fig. 1). Galactic absorption lines at these frequencies, detected in the past 3 years, have rather broad profiles similar to those of the 14-cm H-emission line; and, except for OH near the galactic centre, the intensities of the hyperfine components are compatible with populations of levels in thermodynamic equilibrium[5]. The emission lines, by contrast, show a number of remarkable features.

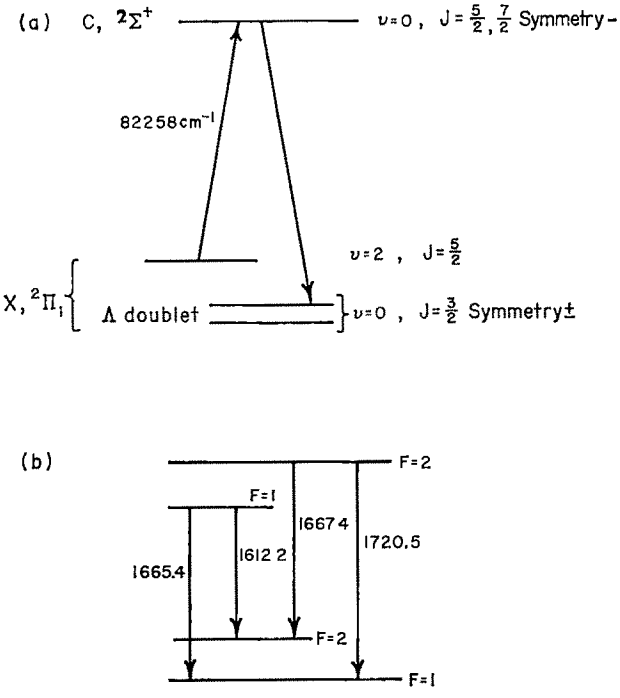

Fig. 1. Portion of level diagram of OH molecule: (*a*) Ground state and electronically excited state *C*. *J*, Total angular momentum quantum number (excluding nuclear spin), *v*, vibrational quantum number. (*b*) Hyperfine structure of Λ-doublet, frequencies in Mc/s. $F = J \pm \frac{1}{2}$

The lines are extremely narrow, the corresponding kinetic temperatures being often less than 50° K; the lines are multiple, as many as seven components separated by 10–15 kc/s being observed in one case[3]; the 1,665-Mc/s line from *W*.3 is linearly polarized by up to 37 per cent and is up to twenty-five times as intense as the 1,667-Mc/s line, whereas, if the populations of the hyperfine levels follow the Boltzmann distribution, the 1,667-Mc/s line should be 1·8 times as intense as the 1,665-Mc/s line; the emission lines are sometimes associated with absorption lines, the frequencies of the latter being less than those of the former by an amount corresponding to 10–15 km/s; the widths of the absorption lines are of the same order as those of the emission lines, and the intensities of the absorption lines are as predicted for a Boltzmann distribution; all the sources are closely associated with thermal continuum sources, some of which are known to be H-II regions.

Although Weaver *et al.*[1] left open the possibility that the emission lines may come from something other than hydroxyl ('mysterium'), Weinreb *et al.*[2] consider the lines to arise from OH excited in some anomalous way. Lines close to three of the four hyperfine components have now been observed in emission from radio sources, and it seems most unlikely that any other emitter should have so closely similar a spectrum.

An optical pumping mechanism for the anomalous excitation of OH is suggested in this communication. Zuckerman *et al.*[3] have observed that none of the frequencies of $n \rightarrow n-1$ transitions of excited hydrogen coincides closely with the frequencies of the OH lines. There is none that coincides with a transition between rotational levels of $X\ ^2\Pi_i$, $v = 0$; nor is there any coincidence with transitions between different vibrational levels of $X\ ^2\Pi_i$. There seems, however, to be an extremely close coincidence between $Ly - \alpha$ ($\lambda = 1216$ Å, wave number 82,259 cm^{-1}) and the transition $X\ ^2\Pi_i$, $v = 2$, $J = 5/2 \rightarrow C^2\Sigma^+$, $v = 0$, $J = 5/2$, 7/2, between a vibrationally excited state of $X\ ^2\Pi_i$ and the electronically excited state $C^2\Sigma^+$. The levels concerned are shown in Fig. 1. Unfortunately, this part of the spectrum of OH, which lies between 1000 Å and 1700 Å, has not so far been observed; the wave number of the transition (82,258 cm^{-1}), as calculated from the data given by Wallace[6], is within 1 cm^{-1} of $Ly - \alpha$.

It is therefore suggested that OH absorbs radiation from the thermal source, giving the $v = 2$ level of the X ground state an appreciable population, and that absorption of $Ly - \alpha$ then populates the $C^2\Sigma^+$, $v = 0$, $J = 5/2$, 7/2 state. (Carrington[7] has shown that OH can be formed in some circumstances in vibrationally excited states by irradiation of water with $Ly - \alpha$.) The symmetry selection rules permit an electric dipole transition from this C state to the upper, but not to the lower, of the Λ-doublet levels. Furthermore, it is found that H-α radiation from H-II regions can be polarized. It may be expected that there are magnetic fields in these regions and that $Ly - \alpha$ is also polarized; it would therefore be possible for the Zeeman sub-levels of the hyperfine levels to be unequally populated.

Conditions under which the suggested mechanism could produce the observed phenomena would seem to exist close to the ionization-shock front believed to form the boundary of an H-II region[8]. As such a front advances, at 10–20 km/s, into the surrounding cloud of cold atomic hydrogen, the gas suddenly becomes almost completely ionized and acquires a velocity of 10–20 km/s. OH in the shock front will be irradiated with both thermal and $Ly - \alpha$ radiation; in front of the shock, $Ly - \alpha$ will be absorbed and broadened by neutral atomic hydrogen and will not be so effective in selective optical pumping, while the cold OH will absorb thermal radiation at microwave frequencies differing from the mean frequencies of the emission lines by amounts corresponding to the shock speed. Behind the shock the temperature of OH will rise to about 10^4 °K, and the spectrum will merge with the thermal emission at that temperature.

To summarize, absorption of $Ly - \alpha$, followed by radiation from the excited C-state, can give abnormal populations in the upper states of the Λ-doublet; conditions in which narrow emission lines associated with slightly displaced narrow absorption lines can arise seem to occur in the ionization-shock front at the boundary of an H-II region. No other transitions of atomic hydrogen have frequencies that nearly coincide with any in the spectrum of OH. Details of the suggested mechanism are being investigated.

PHYSICS

Buoyancy and Stable Levitation of a Magnetic Body immersed in a Magnetizable Fluid

THIS communication concerns the nature of some peculiar forces experienced by a body immersed in magnetic fluid when the body is a source of magnetic field. Prediction and experimental demonstration are given of the stable 'fluidmagnetic' levitation of a permanent magnet at an interior region of the fluid.

It is possible to make a permanent suspension of a finely divided ferro-magnetic solid in a carrier liquid to produce a fluid that responds strongly to a non-uniform applied magnetic field[1]; such fluids are produced and studied in our laboratory—the range of initial permeability $\mu=(\partial B/\partial H)_0$ so far obtained is $1 < \mu < 2$ corresponding to fluids whose ferric induction $M=B-H$ at saturation in units of gauss is $0<M<730$. The fluid is a colloidal dispersion in which the typical particle size is but 100 Å with the number density of the particles being of the order of 10^{17}/c.c. In situations of fluidstatics and fluiddynamics the fluid behaves like a homogeneous Newtonian liquid even though it has the additional characteristic of an appreciable initial permeability in response to an applied magnetic field; the viscosity of these fluids is essentially independent of the field.

The net force acting on a body immersed in stationary magnetic fluid under the influence of gravity, but in the absence of magnetic field sources external to the body, is found from the following integrations of force over the volume V and the surface S.

$$\mathbf{F} = -\mathbf{z}\int_v \rho_b\, g\,dV - \int_s p\mathbf{n}dS$$

Here $\mathbf{z}$ is the unit vertical vector, ρ_b is the density of the body which will be assumed constant hereafter, g is the acceleration of gravity, p is the fluid pressure, and $\mathbf{n}$ is the unit vector oriented outward from any differential surface element dS. Evaluation of the surface integral now requires an expression for the pressure and this is considered next.

A treatment has been given of the fluid mechanical relationships that govern the motion and pressure distribution of magnetic fluids in the presence of an applied magnetic field[2]. It was found possible to derive an augmented Bernoulli relationship which may be expressed as follows to apply at any point within the motionless magnetic fluid that surrounds the immersed body.

$$p + p_h - p_m = \text{constant}$$

In this relationship p is ordinary fluid pressure and p_h is a hydrostatic pressure, such that:

$$p_h = \rho\, gh$$

where ρ is density of the magnetic fluid and h is the height in the gravitational field, while p_m, termed the 'fluidmagnetic pressure', is given by the following expression:

$$p_m = \frac{1}{4\pi}\int_0^H M dH$$

M is the ferric induction, a property of the fluid which is dependent on the magnetic field H. It can easily be seen, since $M \geqslant 0$ for any H, that the magnetic pressure increases when H increases. The equation is written in cgs units wherein M is expressed in gauss and H in oersted, so the numerical value of p_m is expressed in units of dynes/cm^2.

Stated verbally the magnetostatic form of the augmented Bernoulli relationship tells that the sum of ordinary pressure plus a hydrostatic pressure minus the fluidmagnetic pressure is a constant anywhere within the motionless fluid.

Elimination of ordinary pressure p from the force expression, followed by application of Gauss's divergence theorem to convert the surface integrals to volume integrals for the case of uniform gravitational field g and fluid density ρ, gives on recognizing that the gradient of the Bernoulli constant is zero and $\nabla h=\mathbf{z}$ that:

$$\mathbf{F} = \mathbf{F}_m + \mathbf{F}_b$$

where

$$\mathbf{F}_m = -\int_s p_m \mathbf{n} dS = -\frac{1}{4\pi}\int_0^H\int_s \mathbf{n} M dH dS$$

$$\mathbf{F}_b = gV(\rho - \rho_b)\mathbf{z}$$

$\mathbf{F}_m$ above represents a general expression for the fluidmagnetic force experienced by the immersed body while $\mathbf{F}_b$ is the usual expression for the buoyancy (Archimedes' principle) minus the weight.

If the permeability of the fluid may be regarded as constant, then $M=(\mu-1)H$ and the expressions for fluidmagnetic pressure and force become, respectively:

$$\left.\begin{aligned} p_m &= \frac{\mu-1}{8\pi}H^2 \\ \mathbf{F}_m &= -\frac{1}{8\pi}(\mu-1)\int_s H^2 \mathbf{n} dS \end{aligned}\right\} \mu = \text{constant}$$

In this special case of constant permeability the fluidmagnetic pressure at a point varies quadratically with the local magnitude of magnetic field and thereby illustrates the more general relationship already noted. With $\mu=1{\cdot}94$ and $H=395$ oersted the computed value of p_m is 5,809 dynes/cm^2, which is appreciable compared with the ordinary hydrostatic pressure in a small vessel of liquid.

Due to the general property of the fluidmagnetic pressure to be high where the magnitude of the magnetic field is high the possibility exists that a distribution of field might be found giving $\mathbf{F}=0$ and thereby producing a fluid magnetic force equal and opposite to the buoyant weight with the end result that a material object is levitated. Fig. 1 is an X-ray photograph through the opaque fluid that demonstrates such a means of levitation; a ceramic permanent magnet in the shape of a disk, having density $\rho_b=4{\cdot}7$, and immersed in magnetic fluid the density of which is but $\rho=1{\cdot}2$, is levitated in the Earth gravitational field above the bottom of the container holding the fluid. The magnetic fluid has permeability $\mu=1{\cdot}94$. The disk is magnetized in the direction normal to its circular faces. Hall probe measurement shows that it produces a magnetic induction of 395 gauss at a point adjacent to the centre of a face.

Taken together, the plan and elevation views illustrate that the levitation is about an interior point of the fluid. It may be understood, due to the greater magnetic permeability of the fluid compared with the permeability of the non-magnetic surroundings, that the magnet field lines which emanate from and end on the magnet will be more compressed between the magnet and a nearby wall than between the magnet and a more distant wall. Then, due to the nature of the fluidmagnetic pressure and its dependence on field magnitude, it follows that there will be repulsion from any wall. The magnetic body, therefore, seeks an interior point equidistant from all parts of the boundary between fluid and its surroundings (considered to be non-magnetic) such that stable equilibrium attains. A small displacement of the magnet in any direction from its equilibrium position is then accompanied by a positive restoring force.

Further investigation of this and related phenomena, the relationship to Earnshaw's theorem[3], and detailed results of quantitative experimentation have been completed and

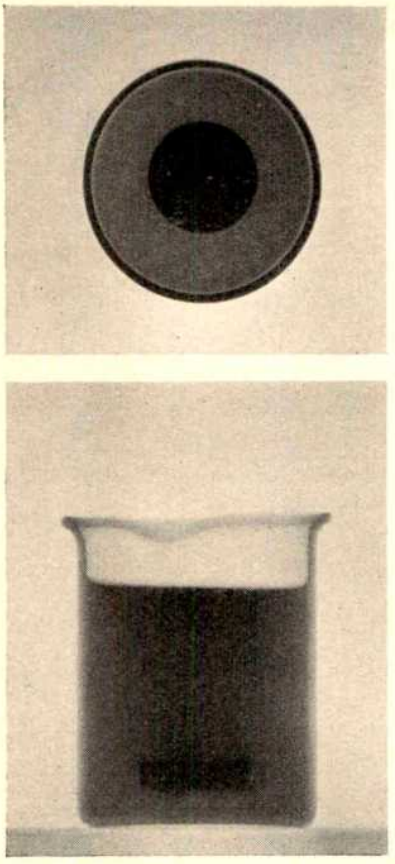

Fig. 1. Plan and elevation X-ray photographs of a disk-shaped permanent magnet immersed in a finite volume of magnetizable fluid. The fluid has a uniform density of 1·2 g/cm³ while the density of the magnet is greater and measures 4·7 g/cm³. The magnet is levitated against gravity and repulsed from the fluid's boundaries to a position of stable equilibrium at an interior region of the fluid space

will be described in another communication. This work is supported in part by the Fluid Physics Branch, National Aeronautics and Space Administration, Research Division, Office of Advanced Research and Technology.

Meissner Effect in a Classical Electron Gas

M. v. LAUE[1] pointed out that thermodynamics can be applied to a superconductor only because it has, by displaying a Meissner effect, a unique state in a magnetic field. The classical electrodynamics of a perfect conductor, however, yields an ambiguous state[1], but only if acceleration effects are neglected. Classical statistics of a free-electron gas give a unique state of zero current (theorem of van Leeuwen[2]) independent of the external magnetic field. It has never been shown, however, how a magnetic field can enter the electron gas without the assumption of surface friction[3].

There are three possibilities: (1) The concept of a gas of classical free electrons is a contradiction *per se*; (2) classical thermodynamics in which the magnetic field does not enter because of van Leeuwen's theorem, and classical electrodynamics contradict each other; (3) van Leeuwen's theorem is not correct. It is the aim of this note to show that the third alternative is true.

The proof of the theorem[2] has neglected magnetic interaction. Including it, the energy law becomes

$$\sum_i \left\{ \frac{m_i}{2}\vec{v}_i^{\,2} + \frac{e_i}{c}\vec{v}_i\left(\frac{1}{2}\vec{A}_i^{\,\mathrm{int}} + \vec{A}_i^{\,\mathrm{ext}}\right) + e_i\left(\frac{1}{2}\varphi_i^{\,\mathrm{int}} + \varphi_i^{\,\mathrm{ext}}\right)\right\} = \text{constant} + \int^t \varepsilon\, dt \quad (1)$$

m_i = mass, e_i = charge, $\vec{v}_i$ = velocity of the particles, $\vec{A}_i$ = vector potential at the momentary positions of the particles defining the internal (int) or external (ext) magnetic field, φ_i = scalar potential. ε is the energy which has to be submitted per sec to the external current system in order to yield external fields which are constant in time in spite of the interaction with the particles.

In the equilibrium case, $\varepsilon = 0$. Evaluating the maximum of entropy for constant left side of equation (1) in the usual way (internal interaction terms are to be duplicated) one obtains a velocity distribution proportional to

$$\exp\left(-\frac{1}{2mkT}\left\{\left(m\vec{v} + \frac{e}{c}\vec{A}\right)^2 - \frac{e^2}{c^2}\vec{A}^2 + 2m\varphi\right\}\right)$$

with $\vec{A} = \vec{A}^{\,\mathrm{int}} + \vec{A}^{\,\mathrm{ext}}$; $\varphi = \varphi^{\,\mathrm{int}} + \varphi^{\,\mathrm{ext}}$

The mean velocity is found to be

$$\vec{v} = -\frac{e}{mc}\vec{A} \quad (2)$$

This is London's equation of the Meissner effect. This effect, therefore, is not a basic quantum phenomenon, as stated by several authors[4,5].

Equation (2) also holds in the case of Bose or Fermi statistics. This removes a further difficulty which has never been mentioned. The old proof of van Leeuwen's theorem can also be applied, word by word, to non-classical statistics. If the theorem was valid, the super-electrons which produce a Meissner effect would obey, apparently, no statistics at all.

Measurement of the Absolute Disintegration Rate of Technetium-99*m*

TECHNETIUM-99*m* is becoming an important tracer for many diagnostic investigations; for example, brain scanning and thyroid scanning[1,2]. Its chief advantages are that it has a short half-life and emits an essentially mono-energetic γ-ray which is only slightly internally converted. Hence quite large activities of technetium-99*m* can be safely administered to patients. So far this nuclide has only been assayed by comparing it with a standard of some other nuclide—for example, cobalt-57 (ref. 3)—and no absolute measurements have been reported. However, as will be shown here, it is possible to make an absolute measurement by the $4\pi\beta$-γ coincidence technique[4]. (The National Physical Laboratory plans to distribute standards of technetium-99*m*, calibrated by this technique, in October 1966, to users within 12 h travelling time of Teddington.)

The decay scheme of technetium-99*m* is shown in Fig. 1. The internal conversion coefficients of the transitions

γ_1 and γ_3 are very large and that for γ_2 is approximately 0·1. If coincidences are observed between the transition γ_1 detected in the β counter and γ_2 in the γ counter, the relationship between N_0, the absolute disintegration rate, and the observed β count rate N_β, γ count rate N_γ and the coincidence count rate N_c is:

$$\frac{N_\beta N_\gamma}{N_c} = N_0\left[a + (1-a)\,\varepsilon_{\beta 3}\frac{\alpha_3}{1+\alpha_3} + \frac{1-\varepsilon_{\beta 1}}{\varepsilon_{\beta 1}}\left\{\frac{a\alpha_2\varepsilon_{\beta 2}}{1+\alpha_2} + \frac{(1-a)\alpha_3\varepsilon_{\beta 3}}{1+\alpha_3}\right\}\right]$$

multiplied by:

$$\left[1 + \frac{1-a}{a}\cdot\frac{1+\alpha_2}{1+\alpha_3}\cdot\frac{\varepsilon_{\gamma 3}}{\varepsilon_{\gamma 2}}\right]$$

also:

$$\frac{N_c}{N_\gamma} = \varepsilon_{\beta 1}$$

where $\varepsilon_{\beta 1}$ is the efficiency of the β counter to the 2 keV transition γ_1, $\varepsilon_{\beta 2}$, $\varepsilon_{\beta 3}$ are the efficiencies of the β counter to conversion electrons from the transitions γ_2 and γ_3, the total internal conversion coefficients of which are α_2 and α_3 respectively, and $\varepsilon_{\gamma r}$ is the efficiency of the γ counter for the rth γ ray. Since $(1-a)\approx 0{\cdot}01$, $\alpha_3 \approx 30$, $\varepsilon_{\gamma 3}\approx\varepsilon_{\gamma 2}$, and for the sources used $\varepsilon_{\beta 2}\approx\varepsilon_{\beta 3}=\varepsilon_\beta \geqslant 0{\cdot}95$, equation 1 can be reduced to:

$$\frac{N_\beta N_\gamma}{N_c} \approx N_0\left[1 + \frac{1-\varepsilon_{\beta 1}}{\varepsilon_{\beta 1}}\cdot\varepsilon_\beta\left\{\frac{a\alpha_2}{1+\alpha_2} + \frac{(1-a)\alpha_3}{1+\alpha_3}\right\}\right]$$

Hence if $\varepsilon_{\beta 1}$ is varied without altering ε_β, extrapolation to $\varepsilon_{\beta 1}=1$ gives the absolute disintegration rate N_0.

Using this method sources of technetium-99*m* were measured. The efficiency of the β counter to the conversion electrons from the γ_1 transition was varied by altering the counter voltage, and to ensure that this procedure did not affect the value of ε_β, all measurements were made within the range of the normal β plateau. A plot of the observed quantity $\frac{N_\beta N_\gamma}{N_c}$ per mg of solution used in source preparation against $\frac{1-\varepsilon_{\beta 1}}{\varepsilon_{\beta 1}}$ for six different sources is shown in Fig. 2, and the statistical error on the intercept at $\frac{1-\varepsilon_{\beta 1}}{\varepsilon_{\beta 1}} = 0$ is ± 0·3 per cent. The overall systematic error on the absolute disintegration rate was estimated as ± 3 per cent. This error includes an allowance for the assumed linearity of the extrapolation of the data shown in Fig. 2.

The technetium-99*m* used in this measurement was obtained from a molybdenum-99 generator supplied by the Radiochemical Centre, Amersham. The molybdenum-99 was absorbed on an alumina column as ammonium molybdate, and technetium-99*m*, the daughter of molybdenum-99, was eluted with an isotonic saline solution.

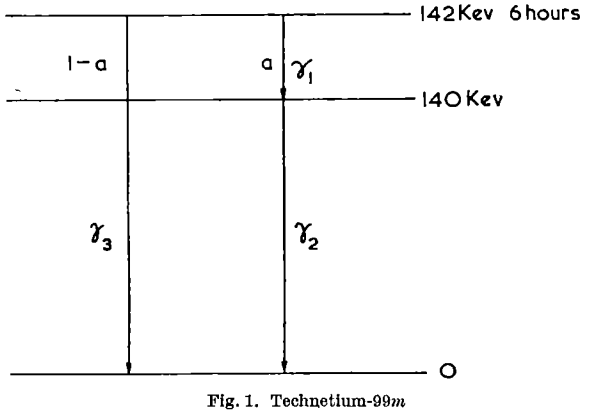

Fig. 1. Technetium-99*m*

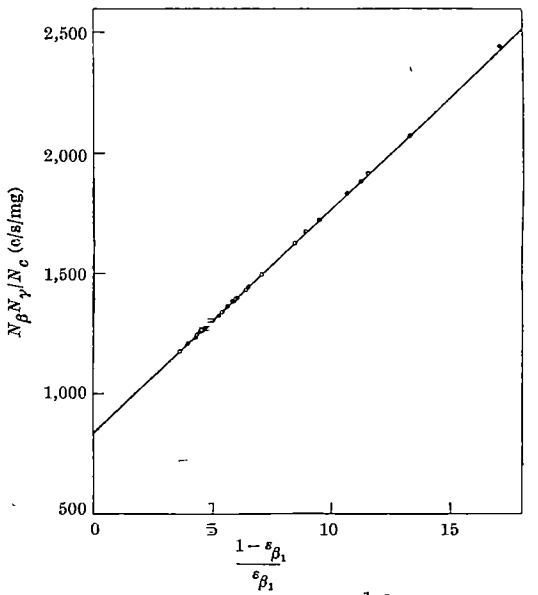

Fig. 2. Plot of $N_\beta N_\gamma/N_c$ against $\frac{1-\varepsilon_{\beta_1}}{\varepsilon_{\beta_1}}$

The purity of the technetium-99*m* was checked by γ-ray spectrometry. The molybdenum-99 content was less than 0·05 per cent and no other γ-emitting nuclides were detected. In subsidiary experiments it was shown that there was no adsorption of carrier-free technetium-99*m* as pertechnetate ion in isotonic saline solution on to the siliconed glassware used in the standardization.

The half-life of technetium-99*m* was measured using an ampoule of sodium pertechnetate in isotonic saline solution in a re-entrant high-pressure γ ionization chamber, the readings being taken over a period of five half-lives. The purity of the technetium-99*m* was again measured by γ-ray spectrometry at the end of the half-life measurements and at this time the molybdenum-99 contaminant was less than 0·005 per cent. The value obtained for the half-life was 6·006$_7$ h with a standard deviation of 0·01 per cent, and an estimated overall systematic error of ± 0·03 per cent.

We thank Dr. P. J. Campion for suggesting that technetium-99*m* could be measured by the 4πβ-γ coincidence technique and Miss R. Birdseye, Miss F. H. Hughes and K. Fordham for help with the experimental work.

A Silver-110*m* Contamination in Scintillation Detector Shielding

We have recently completed the third of three similar lead shielding assemblies for sodium iodide (thallium activated) γ-detectors, used in conjunction with multichannel pulse height analysers. These equipments are used for the assay of biological and other samples arising from statutory monitoring responsibilities connected with the disposal of radioactive waste from nuclear sites.

Many of the samples assayed contain low levels of radioactivity, and the latest detector assembly has been designed to have a low background count rate, and hence

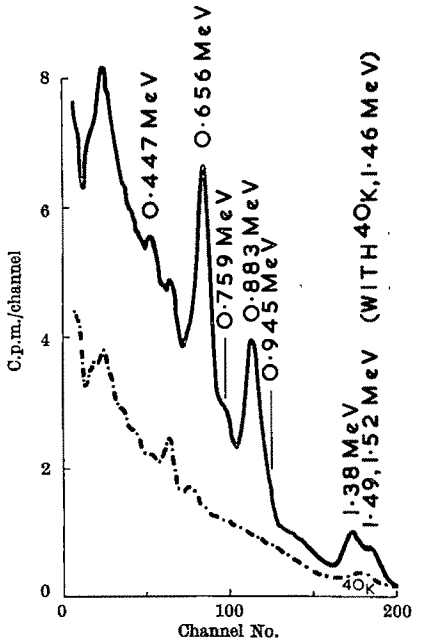

Fig. 1. Background spectra obtained from identical lead shields. ——, Lead contaminated with silver-110*m*; — · — · —, uncontaminated lead

greater sensitivity. Preliminary checks of the detector system in an existing shield were encouraging, indicating a reduction in background count rate from about 350 c.p.m. to 250 c.p.m. over the energy range 50 keV–1·6 MeV.

Completion of the assembly in a newly erected shield resulted in a surprisingly high background rate of 560 c.p.m., and a short spectrometric count of the roughly calibrated detector showed the presence of two photopeaks in the 500 keV–1 MeV region. Since this laboratory uses millicurie quantities of caesium-134 for research purposes, our first reaction was that, in spite of careful control of this nuclide, the detector had been contaminated with caesium-134, probably by a very small quantity, with very good counting geometry.

The detector assembly was dismantled, cleaned and re-assembled, but these measures failed to reduce the high background count rate, indicating contamination of the lead shielding. This shield was constructed with 4 in. × 4 in. interlocking lead bricks to Atomic Energy Research Establishment specification 420, and had internal dimensions of 18 in. × 18 in. × 22 in. Each wall of the shield was separately exposed to the detector, and this showed the contamination to be uniformly distributed over the bricks. Surface washing of the bricks indicated that the contamination was homogeneous within the lead.

After careful calibration of the energy response of the detector, and a long count, photopeaks due to the γ-emissions of silver-110*m* were identified. The suppliers of the bricks were most co-operative, but claimed not to use silver-110*m* within their plant, and it was therefore assumed that contamination was present before the bulk lead reached the brick makers. We concluded that radioactive silver was possibly used by the mining company in a tracer method of investigating the efficiency of silver extraction processes.

Whatever the source of contamination, a man-made nuclide was introduced which affected subsequent use of the material. The quantities involved are in no way hazardous, being below the threshold sensitivity of normal health physics instruments, and, with a half-life of 270 days, will have little effect in this particular application after about 6 years' decay time.

When encountered in γ-spectrometry shields, such contamination is easily identified and removed (by replacement of the shield), but when it occurs in the shield of a single-channel analyser system, or other γ-sensitive detector, the contamination might not be identified and remedied, and could result in reduced sensitivity. Moreover, the cause of the slowly falling background count, due to the comparatively long half-life of silver-110*m*, would probably not be recognized, and could be wrongly attributed to other factors such as electronic instability, thermal drift, etc.

γ-Spectra demonstrating the difference between contaminated and uncontaminated shields are shown in Fig. 1, and it is hoped that this report will help other users (and manufacturers) of similar shields to avoid the delays and expense incurred as a result of such contamination.

Rotation and the Inverse Square Law

CONSIDER a cloud-like distribution of matter, of volume v, and with average density ρ which is roughly uniform; and which rotates with angular velocity Ω. The angular velocity may vary with time. Let C be the origin of a frame of reference fixed in the distribution and P any point of the cloud.

The acceleration of P will contain among others the term $\Omega \times [\Omega \times \vec{CP}]$. Writing this term as $\mathbf{f}$ we find curl $\mathbf{f} = 0$ and div $\mathbf{f} = -2\Omega^2$. From these we obtain $\mathbf{f} = -\nabla\varphi$, $\nabla^2\varphi = +4\pi\lambda\rho$, where $2\pi\lambda\rho = \Omega^2$.

This is Poisson's equation for uniform density with $\mathbf{f}$ taking the role of the usual newtonian gravitational force. Hence, adopting the usual mathematical arguments for Poisson's equation in reverse, we have:

$$\mathrm{div}\left(\mathbf{f} + \int_v \frac{\gamma\rho\mathbf{r}}{r^3}\,d\tau\right) = 0$$

where $d\tau$ is a volume element of v, $\mathbf{r} = \vec{PQ}$ and Q is any point other than P.

Integrating

$$\mathbf{f} = -\int_v \frac{\gamma\rho\mathbf{r}}{r^3}\,d\tau + \mathrm{curl}\,\mathbf{H}$$

So the acceleration term $\mathbf{f}$ is equivalent to the distribution being composed of gravitating material according to the inverse-square law, as well as subject to a field $\mathbf{H}$. Hence we may look on the distribution as gravitating matter subject to a possible additional field $\mathbf{H}$, instead of having the contribution due to $\Omega \times [\Omega \times \vec{CP}]$ from the acceleration.

These results are capable of considerable extension.

GEOPHYSICS

Convergence and Divergence in Gravity and Magnetic Interpretation

A RECENT communication by Prof. B. S. R. Rao and I. V. Radhakrishnamurty[1] creates a misleading impression (more particularly for the case of a sphere) that the depth of a body can be easily interpreted from the gravity (or magnetic) data by finding out the critical radius of the circle beyond which average radial gravity (or magnetic) value diverges. In actual practice this interpretation is not possible because for a body of finite dimensions (at any depth) the average radial value can never be infinite (this is obvious from physical reasons) however large a circle we may choose.

This apparent contradiction in theory and practice has occurred because the authors have ignored the restriction inherent in the expansion of the function $\bar{g}(r)$. The expansion for $\bar{g}(r)$ is permissible only in the circle of convergence and the representation is no more valid beyond that region. Since this series is an equivalent form of Taylor's series, the radius of convergence of this series for $\bar{g}(r)$ is also the distance from the centre of the circle to the closest singular point. In the case of the sphere cited this would mean that the expansion (and the interpretation based on that expansion) is incorrect for all values of $R > Z$. The ratio test clearly shows that the given series for the case of the sphere is absolutely convergent for all values of $R < Z$ (instead of $R < 0{\cdot}88\ Z$). It can also be added that the convergence/divergence of the series inside/outside this region of convergence is not a function of the number of terms chosen.

J. G. NEGI

National Geophysical Research Institute,
Hyderabad-7 (A.P.).

[1] Rao, B. S. R., and Radhakrishnamurty, I. V., *Nature*, **206**, 179 (1965).

DR. NEGI'S criticism seems to have been based on a misreading of the purpose of our communication[1]. What we actually meant to convey was that the average radial gravity $\bar{g}(r)$, expressed in Taylor's expansion or in any of its allied forms, cannot always be accepted in view of its oscillatory character. Thus such representation should be made with some caution and only below a certain range of radius, depending on the depth of the body and the location of the point of measurement.

Secondly, Dr. Negi's argument that the expansion for $\bar{g}(r)$ is permissible only in the circle of convergence and that the radius of this circle should be Z and not $0{\cdot}88\ Z$ is clearly untenable. If we extend this argument it means that Taylor's expansion is valid only for its closest singular point, which would result in the divergence of the series for all positive values of r, which is not correct.

Dr. Negi has further pointed out that the convergence/divergence of the series inside/outside this region of convergence is not a function of the number of terms chosen. One can easily disprove this argument by adding terms, one by one, and finding out the value of $\bar{g}(r)$.

Equatorial Ionospheric Drifts

A NUMBER of authors[1-3] have shown that near the magnetic equator ionospheric drifts occur, in both the E and F regions, which are mainly westwards by day and mainly eastwards by night. Results for F region drifts at Ibadan have been given by Skinner, Lyon and Wright[1] for the International Geophysical Year (IGY) (1957–58). These show that for quiet days during equinox periods at sunspot maximum, the median velocity of drift reached a value of about 100 m/sec eastwards at midnight and a value of about 76 m/sec westwards at noon. The changes in direction occurred rather rapidly at about 0700 in the morning and at about 2000 in the evening.

A similar series of observations were made at Ibadan during the International Years of the Quiet Sun (IQSY) (1964–65), when solar activity was at a minimum. The results for October 1964 are shown in Fig. 1 in the form of a mass plot of the diurnal variation. The circles indicate median values for each hour, and the smooth curve estimates the median diurnal variation. The form of the variation is very similar to that obtained during the IGY, with mainly westward velocities by day and mainly eastward velocities by night, and with the change-overs occurring at very nearly the same times. The magnitudes of the drift velocities are, however, little more than half those observed in the IGY, being about 55 m/sec eastwards at midnight, and about 41 m/sec westwards at noon. A comparison of the two variations is shown in Fig. 2*a*. Very similar results were obtained during the World Geophysical Interval in March 1965, and a comparison of the variation for this period with the IGY variation is shown in Fig. 2*b*.

For simplicity only the smooth diurnal curves, fitted by visual estimation, are shown in Fig. 2. The uncertain-

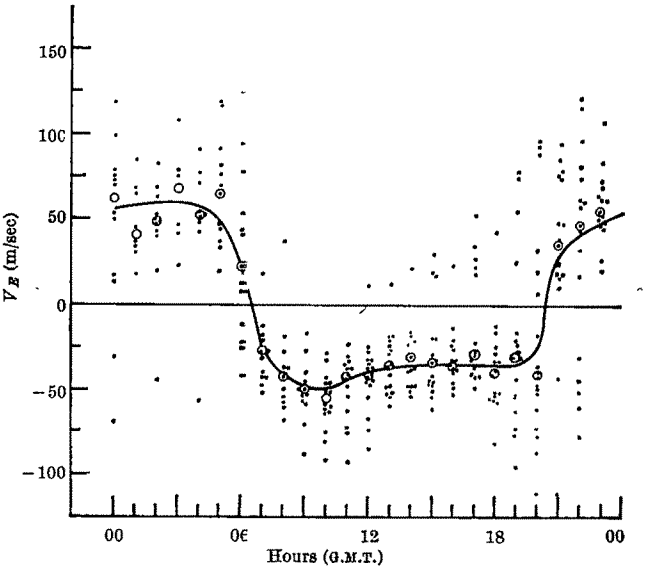

Fig. 1. Mass plot of V_E, the eastward component of F-region drift velocity observed at Ibadan during October 1964. Circles indicate hourly medians; the smooth curve is a visually estimated diurnal variation

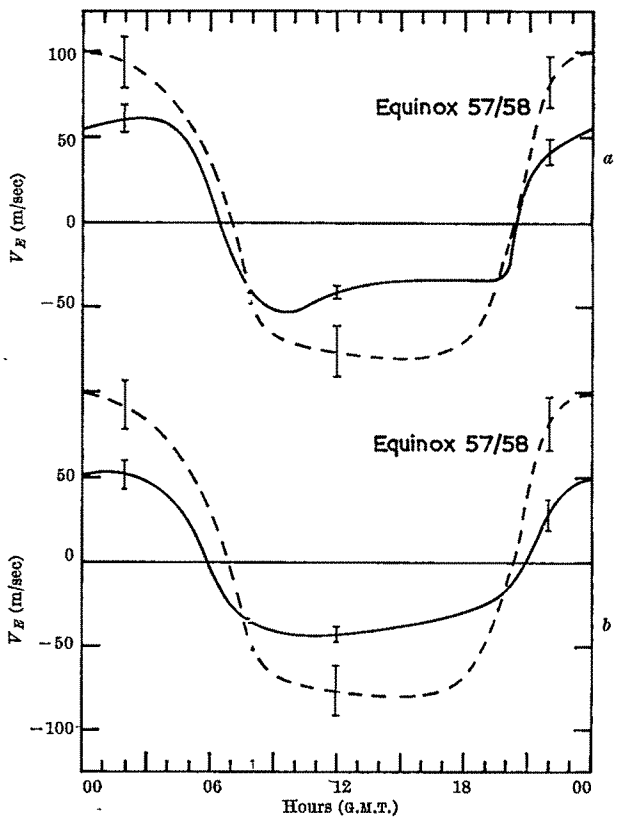

Fig. 2. Comparison of results for V_E obtained during the International Geophysical Year (broken lines) and the International Years of the Quiet Sun (continuous lines) at equinox periods. *a*, comparison for October 1964; *b*, comparison for March 1965. The error bars indicate the estimated uncertainty of values on the fitted curves shown

ties in these fitted curves are indicated by error bars, representing estimated standard errors. The large variability from day to day shown in Fig. 1 is believed to be mainly due to a real variability in the drifts rather than to measurement errors. For the IQSY results the standard error of a value on the fitted curve is estimated at ± 3 m/sec near noon, and at ± 8 m/sec near midnight. The uncertainty on the IGY curve is somewhat greater, and both near noon and midnight the standard error is estimated to be about ± 15 m/sec.

It thus appears that *F*-region drift velocities have decreased significantly and substantially from sunspot maximum to sunspot minimum: near noon, from about 75 ± 15 m/sec to about 41 ± 3 m/sec, and near midnight from about 100 ± 15 m/sec to about 55 ± 8 m/sec. The ratio of decrease is about 1·8 in both cases.

If the observed drifts are produced by electrodynamic forces in the manner suggested by Martyn[4], it is not obvious why such a change in drift velocities should occur. Although conductivities and electric currents vary with the solar cycle, tidal velocities and electric fields, and hence electrodynamic drift velocities, should, at least on a simple model, remain constant. From the present evidence it appears, however, that the *F*-region drift velocity varies almost as much as the daily range of the horizontal component of the Earth's magnetic field, ΔH. At Ibadan this decreased by a factor of about 2·1 between the solar maximum of the IGY and the solar minimum of the IQSY, which may be compared with the ratio of 1·8 for drift velocity. It is interesting also to compare this result with the evidence obtained by Osborne and Skinner[5] of a correlation between drift velocity and ΔH even on a day-to-day basis.

In the *E*-region we have found no evidence of any solar-cycle variation of drift velocity similar to that found in the *F*-region. Thus the drift velocity in the *E*-region near noon was 42 ± 3 m/sec in October 1964 and 39 ± 5 m/sec in March 1965. The IGY data are less numerous, but from eighteen values obtained between 10 and 14 h in equinox months at sunspot maximum the median value is 45 ± 10 m/sec. The median of seventeen values obtained between 10 and 14 h in winter months is similarly 51 ± 6 m/sec. It thus appears that if there is any change in *E*-region drift velocity with sunspot activity, it is considerably less than occurs in the *F*-region. This would seem to be consistent with the results reported by Rao and Rao[3].

It may be remarked in conclusion that the IGY data and the IQSY data were analysed by somewhat different methods. For the former the usual full correlation method was used, but for the more recent data a method originally suggested by Briggs and Spencer[6] has been used. Fuller details will be given elsewhere and here we shall only say that we have concluded from numerous test comparisons that there is no appreciable systematic difference between the two methods.

Variation of the Ratio Intensity to Susceptibility in Red Sandstones

As the remanent intensity of magnetization, *I*, of rocks is dependent on the strength of the magnetic field in which it was acquired, an estimate of relative field strengths can be made by comparing the remanent intensities from different rock units which have supposedly acquired their magnetization in a comparable manner[1]. A statistical method that gives an effective mean for each unit would be expected to be capable of revealing broad changes in the strength of the palaeogeomagnetic field. It has been found that the distribution of remanent intensities generally seems to follow the log normal distribution. As the susceptibility, *K*, of red sandstones has been found to be proportional to the amount of iron oxide present[2] the ratio of intensity to susceptibility is partially compensated for variations in the amount and type of magnetic material present. This ratio should be more dependent on the field strength than would be the intensity alone. The geometric means of this ratio have been calculated for a collection of red sandstones obtained from the United States[3,4] mainly from flat lying sites. The results from eighty-two sampling sites in thirty formations are summarized in Fig. 1. It can be seen that the *I*/*K* ratio yields a smoother pattern with age than the *I* plot. It shows a palaeozoic low. The vertical lines give the standard deviation of the geometric site values for the given era.

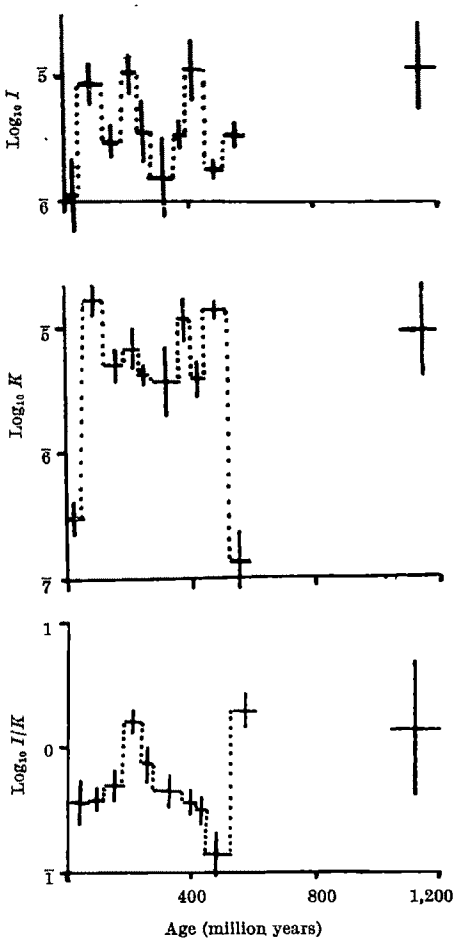

Fig. 1. Log_{10} plots of *I*, *K* and *I*/*K* against age of red sandstones

I thank Prof. S. K. Runcorn for access to his collection of red sandstones.

Azimuthal Variation of U.S. Station Residuals

DEVIATIONS from the Jeffreys–Bullen tables of P times to North American stations in the distance range 32°–100° have been studied recently by Cleary and Hales[1]. The earthquakes on which the investigation was based fell into 3 groups: (1) from the Mid-Atlantic Ridge and Europe; (2) along the west side of South America; and (3) from Alaska to Formosa. The station residuals extracted from the data were observed to vary regionally, in the manner shown by the contours mapped in Fig. 1. After removing these systematic effects, it was found that the remaining residuals were azimuthally dependent for some stations. This is exemplified by the plots reproduced in Fig. 2; the stations concerned have also been mapped

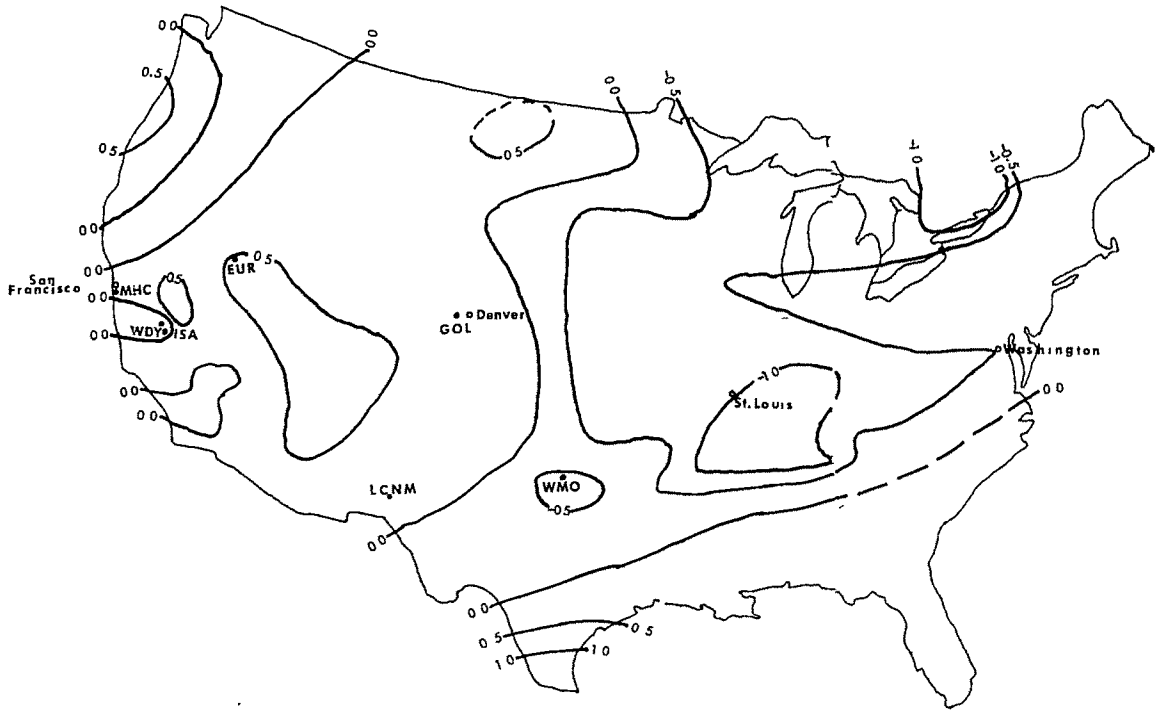

Fig. 1. Residuals for North American stations

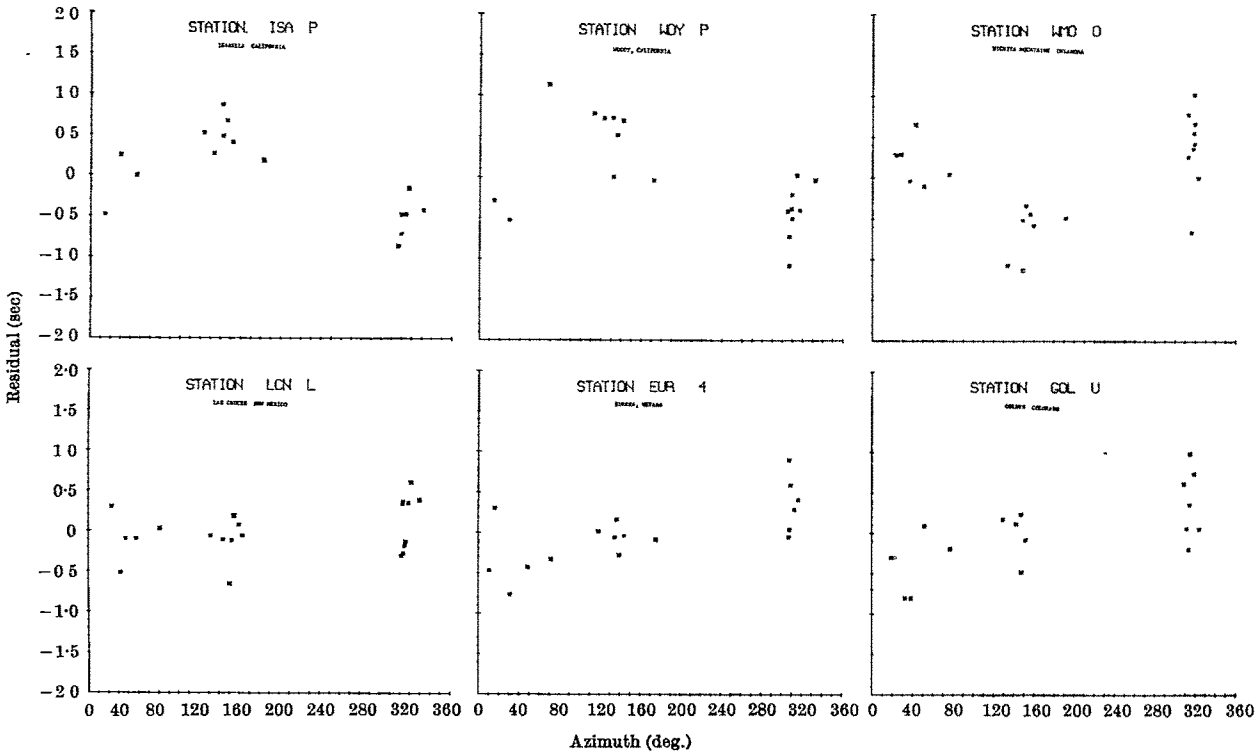

Fig. 2

in Fig. 1 (abbreviations used are those recommended by the U.S. Coast and Geodetic Survey). The residuals between azimuths of 0° and 80°, 100° and 200°, and 280° and 360° are from groups (1), (2) and (3), respectively.

The variation in azimuthal dependence from station to station precludes any possibility that the effect is due to errors in location of epicentres. See, for example, the marked contrast in the azimuthal effects at ISA and LCNM, even though the mean azimuths for each group are virtually the same at both stations.

Azimuthal variations appear to be most marked for stations situated in regions where the contours indicate a fairly rapid change in station residual (ISA, WDY, WMO), and weak or absent for stations in regions of gradual change (LCNM, EUR, GOL). The vectors of maximum azimuthal variation at the strongly affected stations are reasonably consistent with that to be expected from the disposition of the contours. Further investigations of this relationship should provide some indication of the depths at which station delays are introduced.

GEOCHEMISTRY

A Potassium–Argon Age for the Barwell Meteorite

A POTASSIUM–ARGON age has been determined for the olivine-hypersthene chondrite that fell at Barwell, Leicestershire, on December 24, 1965.

Determinations of the potassium content have been made at the British Museum (Natural History) and the Universities of Leicester and Oxford. The results are shown in Table 1, where the errors indicated are standard deviations of replicate analyses.

Table 1

Laboratory	Method	Potassium content (per cent)
British Museum (Natural History) (analysed by A. J. Easton)	Flame photometry using a buffering technique	0·10 ± 0·01
University of Leicester (analysed by M. L. W. Blackley)	Flame photometry using a buffering technique	0·11 ± 0·02
University of Oxford	Flame photometry using a buffering technique. (Triplicate analysis)	0 095 ± 0 002

A neutron activation analysis has also been carried out at the University of Oxford. This yielded a value of 0·096 ± 0·005 per cent potassium. These results are concordant among themselves. Potassium determinations by flame photometry at Cambridge, however, have given the following figures: First run, 0·163 ± 0·005 per cent potassium; second run, 0·162 ± 0·006 per cent potassium. This suggests either that the fragments analysed at Cambridge have been contaminated, or that there are very considerable variations in the potassium content of the Barwell meteorite, or that the fragments analysed in Oxford, Leicester and London have been leached.

It is clear that in any event the potassium content of the Barwell meteorite is rather larger than normal. It has been found that the potassium contents of chondrites (excepting carbonaceous chondrites) cluster quite closely around a value of 0·085 per cent potassium[1], although a few well-substantiated deviations have been noted; for example, the olivine-bronzite chondrite Beardsley which has a potassium content of about 0·1 per cent potassium[2]. It has been suggested that the departure of potassium determinations from the average value of 0·085 per cent potassium should be taken as a rough index of the reliability of the data[3]. Since it seems now, however, that significantly different values can occur, it might prove more profitable to re-examine deviant analyses, especially since analytical methods superior to those used by Edwards[1] or Edwards and Urey[4] are now available.

Argon analyses have been made at Oxford and Cambridge. At Oxford, the meteorite sample was fused with boric oxide flux at about 1,600° C for about 25 min. This produced complete fusion, as was proved by examining thin sections prepared from the fused mass. About 2·5 g of meteorite were used together with nearly the same weight of flux. The gas analysis was made with a Reynolds mass spectrometer. The gases evolved were purified by the usual techniques and measured with spike argon-38. The radiogenic argon-40 content of the meteorite was calculated by isotope dilution and found to be (6·20 ± 0·12) × 10^{-5} c.c. S.T.P./g. The error quoted here includes the uncertainty in the spike calibration. Contamination due to atmospheric argon-40 amounted to 6·5 per cent of the total argon-40 measured.

At Cambridge, the meteorite sample was heated by itself until fusion was complete. This was checked by reheating the sample: no more argon was evolved. After cleaning with a red-hot titanium sponge, the gases were measured with spike argon-38 in an Omegatron mass-spectrometer device. Two samples were run as a check, and gave values of 6·56 × 10^{-5} c.c. S.T.P./g and 6·58 × 10^{-5} c.c. S.T.P./g. There is a probable error of ± 1 per cent in these measurements due to uncertainty in the spike argon volume. The atmospheric contaminations amounted to 9·6 per cent and 10·2 per cent, respectively.

In calculating ages, the partial decay constants for potassium-40 were taken to be: $\lambda_\beta = 4{\cdot}72 \times 10^{-10}$ yr^{-1}; $\lambda_e = 0{\cdot}584 \times 10^{-10}$ yr^{-1}; potassium-40/potassium = 0·0119 atom per cent. With a value for the potassium content of 0·096 per cent, the Oxford results give an age for the meteorite of (4·19 ± 0·06) × 10^9 yr. With a potassium content of 0·1 per cent, the two Cambridge results give ages of (4·30 ± 0·05) × 10^9 yr and (4·31 ± 0·05) × 10^9 yr. Using the Cambridge potassium results instead, with a mean value of 0·163 per cent potassium, the two Cambridge argon determinations then give ages of 3·49 and 3·50 × 10^9 yr, respectively.

Several hypersthene chondrites have been found to give potassium–argon ages which are appreciably shorter than the usual chondrite range of 3·5–4·5 × 10^9 yr. These particular chondrites are also usually found to show signs of shock effects (that is, blackening, veining or brecciation)[5], which may well have caused argon loss. The Barwell meteorite shows no obvious signs of shock effects: the absence of such effects would appear to be supported by its normal age.

We are indebted to the British Museum (Natural History) for permission to quote potassium determinations made there.

OCEANOGRAPHY

Mechanical Behaviour of Metals in Deep Ocean Environments

THE rapidly developing interest in deep ocean engineering makes it necessary to consider possible effects of deep ocean environments on the properties of engineering materials. The principal difference between a deep ocean environment and an environment just below the surface of an ocean is, of course, that in the former there exists a large hydrostatic pressure. It can easily be shown that if the depth from the surface, h, is measured in fathoms, the hydrostatic pressure, P, is given by:

$$P \simeq 3h \text{ lb./in.}^2 \quad (1)$$

This communication considers the changes in mechanical properties which might be expected to result from this hydrostatic pressure. We shall consider first reversible effects, that is, effects which should be observed only when a metal or alloy is stressed while submerged in a deep ocean, and, secondly, possible irreversible effects, that is, property changes which might be caused by deep submergence and persist after the metal or alloy has been removed from the deep ocean environment.

We shall restrict our discussion of reversible effects to metals and alloys which exhibit a ductile-brittle transition, that is, those the behaviour of which changes from ductile to completely brittle over a narrow temperature range. Examples are iron and most of the ferritic steels. For convenience, we shall focus our attention on the simplest possible case, the effect of a hydrostatic pressure on a transition occurring in a series of specimens subjected to uniaxial loading at a constant strain-rate over a range of temperatures embracing the transition. We define the transition temperature as the highest temperature at which completely brittle behaviour can be observed.

According to the present theories of the transition[1,2], the macroscopic yield stress and crack propagation stress are equal at the transition temperature. In the absence of a hydrostatic pressure, let the transition temperature in °K and the macroscopic yield stress at the transition temperature be T_0 and σ_0, respectively. For most materials, including all those such as iron and ferritic steels which have a body-centred cubic crystal structure, the yield stress, σ, and temperature, T, are related by the equation:

$$\sigma \simeq A + \frac{B}{T} \quad (2)$$

where A and B are constants characteristic of the particular material being considered. The parameters σ_0 and T_0 are therefore related by:

$$\sigma_0 = A + \frac{B}{T_0} \quad (3)$$

When a hydrostatic pressure P is applied, it is reasonable to expect that the macroscopic yield stress will be unaffected, since the glide and multiplication of dislocations are governed only by shear stresses. The applied tensile stress required to propagate the crack will, however, be raised in magnitude by P. Thus, a specimen tested at a temperature T_0 in the presence of the hydrostatic pressure P will not behave in a brittle manner. In order to obtain brittle behaviour, the temperature must be lowered to some value T_1 such that the resulting increase in σ is equal in magnitude to P. If this new value of σ is σ_1, we have:

$$\sigma_1 = A + \frac{B}{T_1} \quad (4)$$

$$\sigma_1 = \sigma_0 + P = \sigma_0 + 3h \quad (5)$$

Combining equations (3), (4) and (5) we obtain, putting $T_0T_1 = T_0^2$:

$$\Delta T \simeq \frac{3hT_0^2}{B} \quad (6)$$

where ΔT is the decrease in transition temperature, $T_0 - T_1$, due to the hydrostatic pressure.

Equation (6) predicts that the transition temperature should decrease linearly with increasing depth, and the insertion of typical values of B and a value of T_0 close to ambient temperature shows that for a deep ocean ($h \simeq$ 6,000 fathoms) ΔT should be several tens of degrees. No measurements of ΔT in an actual ocean environment have as yet been reported, but recently one set of laboratory measurements of the effect of hydrostatic pressures up to 20,000 lb./in.^{2} on the ductile-brittle transition temperature of molybdenum have been reported[3]. These showed that in a high strain-rate bend test the transition temperature decreased from about 50° C to 2° C as the pressure was increased from atmospheric to 20,000 lb./in.^{2} (see Table 1).

Table 1. EFFECT OF HYDROSTATIC PRESSURE ON THE DUCTILE–BRITTLE TRANSITION TEMPERATURE OF MOLYBDENUM (REF. 3)

Pressure (lb./in.^{2})	Transition temp.
15 (1 atm.)	50° C
10,000	25° C
20,000	2° C

Thus these experiments confirm the magnitude of the effect predicted in equation (6). They are also consistent within experimental area with the linear dependence of ΔT on h which this equation predicts. A second piece of experimental evidence which supports the existence of this effect in zinc has recently been published by Pugh[4]. He found that the application of a hydrostatic pressure of about 13,000 lb./in.^{2} changed the room temperature tensile behaviour of zinc from completely brittle to ductile. This can, as Pugh points out, be interpreted to mean that the transition temperature is lowered from above room temperature to below it by the hydrostatic pressure. Thus, the theoretical ideas expressed by equation (6), and these two pieces of supporting experimental evidence, leave little doubt that a hydrostatic pressure, such as exists in a deep ocean, can by itself drastically alter the mechanical properties of a metal or alloy.

It is more difficult to predict whether deep ocean submergence should produce irreversible effects on the mechanical properties of metals. Bullen *et al.*[5,6] have recently published the results of some laboratory experiments in which iron and chromium were subjected to pressures of up to 150,000 lb./in.^{2}. He found that the pressurization caused substantial irreversible increases in ductility and decreases in yield stress. At lower pressures comparable with those in deep oceans, few results were obtained, but they suggested that the effect was small or negligible for these pressures. A significant feature of the results of Bullen *et al.* on iron was the observation that the magnitude of the effects obtained were sensitive to the purity of the metal used. The larger effects found in impure iron were interpreted as in some way due to the generation of dislocations at the surfaces of the inclusions. Stresses are, of course, set up at an inclusion-matrix interface under a hydrostatic pressure because the inclusion and matrix have different bulk moduli. If this interpretation is correct, it seems reasonable to expect that the effects may be enhanced in engineering alloys which frequently contain high densities of inclusions. There therefore seems some chance that deep ocean submergence will be found to produce significant irreversible mechanical property changes in metals and alloys.

A programme of laboratory work to be carried out in collaboration with the Naval Applied Science Laboratory, Brooklyn, has recently been initiated to explore both reversible and irreversible changes in the mechanical properties of metals and alloys resulting from the applica-

tion of hydrostatic pressures of the magnitude found in deep oceans.

CHEMISTRY

Complex Formation and Carcinogenicity of Aromatic Compounds

SEVERAL crystalline complexes of aromatic hydrocarbons and related compounds with 1,3,7,9-tetramethyluric acid (TMU) have been prepared[1,2]. These and similar complexes are of interest because of the possibility that *in vivo* complex formation between carcinogens and nucleic acids or their precursors may play a part in chemical carcinogenesis. This possibility has been explored also in investigations of the binding of aromatic hydrocarbons to nucleic acids[3,4].

Measurements of ultra-violet absorption spectra of solutions of the complexes revealed small shifts to longer wave-length but did not allow for conclusions about the nature of the complexes or their possible role in carcinogenesis[2].

In a recent report Pullman *et al.*[5] explored the possibility of other types of complex formation. These involve polarization and dispersion forces, rather than charge transfer earlier emphasized by them[6]. Work at present under way in this laboratory and reported in part[7,8] bears directly on this problem.

A survey of earlier work[9] left no doubt that the purine-aromatic complexes are largely or entirely dissociated in solution. Since the *in vivo* interactions may occur as solid-solid interactions between nucleic acid and carcinogen, rather than in solution, it was important to examine these complexes in the solid state. The fluorescence spectra of a number of aromatic and heterocyclic compounds were measured in a potassium bromide matrix in which they are dispersed as solid solutions or as crystalline solids depending on concentration[10]. The fluorescence excitation and emission spectra of the TMU complexes of three aromatic hydrocarbons[7], and more recently of heterocyclics and substituted aromatics, were also examined. All complexes examined were analytically pure materials; they vary, however, in their TMU content; the pertinent spectral data of these complexes are summarized in Table 1.

The first five complexes listed in Table 1 show shifts to shorter wave-length in comparison with the crystal fluorescence of the parent compounds and to longer wave-length with respect to their solution spectra. Noticeably, α-naphthol and β-naphthylamine do not show any fluorescence wave-length shifts when complexed to TMU and examined in the crystalline state. With the exception of pyrene[7] these fluorescence shifts are not observed, even in concentrated solutions.

The fluorescence emission maxima of the crystalline solids are shifted without comparable changes in excitation maxima; this means that the mirror-image symmetry of excitation and emission, observed for charge transfer complexes[11], is not maintained.

Although solubilization of aromatic hydrocarbons in water increases with increasing electron-donor properties

§ Weak shoulders at shorter wave-length due to solid solution spectra.

of the purine[1] there is no correlation between the electron affinity of the hydrocarbons and the extent to which they are solubilized in water by TMU (ref. 7). These observations lead to the conclusion that the donor-acceptor complexes are not involved.

Liquori *et al.*[12] suggested that polarization bonding may be involved in these complexes. This type of bonding involves a polar component (TMU) and a component that can be polarized. The present findings are in agreement with this type of bonding and some of these conclusions were described in our earlier report[7]. Pullman's recent contribution on this problem[5] is also consistent with this type of bonding.

Since carcinogenic and non-carcinogenic hydrocarbons form complexes of this type and, presumably, interact with nucleic acids[3] the significance of this type of complex formation in chemical carcinogenesis remains to be determined. However, these complexes should be explored further because carcinogenic metabolites of aromatic hydrocarbons have not as yet been isolated.

Several investigators[13–15] have pointed to the formation of coloured charge transfer complexes of aromatic carcinogens with electron acceptors such as 1,3,5-trinitrobenzene as indicative of a relationship between carcinogenicity and π-complex formation. But, if the ionization potential or the energy of the highest filled molecular orbital of the hydrocarbon is plotted against wave-length of the charge transfer band, a straight line is obtained; this has been observed for many hydrocarbons with a series of acceptors[11,16,17].

The correlation drawn by these authors[13–15] is, therefore, another way of implying that there is a relationship between carcinogenicity and the ionization potential or the energy of the highest filled molecular orbital of the aromatic carcinogen.

Inspection of the values for the energy of the highest filled molecular orbitals of a number of aromatic hydrocarbons[18] reveals that the carcinogenic hydrocarbons generally have energy values in the range 0·37–0·52; some carcinogenic hydrocarbons fall outside this range and non-carcinogens fall within this range.

It is clear then that π-complex formation, *per se*, does not correlate directly with carcinogenicity. Other factors, such as molecular size and reactivity at particular sites of the molecule, undoubtedly are also important.

Hot-wire Ignition of *Cyclo*propane/Oxygen Mixtures

EXPLOSION risks with certain anaesthetic gas mixtures can be increased in an operating theatre containing a pressurized oxygen atmosphere (hyperbaric oxygen operating theatre). The use of electrically heated wires for cauterizing raises particular problems as the hot wire can act as a continuous source of ignition.

Although the characteristics of ignition by a hot wire in a *cyclo*propane/oxygen system are complex, it is possible to predict with some confidence the upper limit of wire temperature that can be used.

The basis of the theory of thermal ignition is due to Van't Hoff[1]. According to this theory the condition for thermal ignition of an explosive mixture is the impossibility of thermal equilibrium between the reacting system and surrounding medium being maintained. The qualitative formulation of this condition, as contact between the curve of heat supply and that of heat removal, was first given by Le Chatelier[2].

For thermal ignition by a hot wire the heat supplied by chemical reaction (in a zone radius r_2 surrounding wire radius r_1) can be shown to be:

$$q = A' \exp -\left(\frac{E/R(T_1 + T_2)}{2}\right) \pi (r_2 - r_1) L.Q. \qquad (1)$$

where, taking the particular case of *cyclo*propane/oxygen, A' is the frequency factor[3], E is the Arrhenius activation energy[3], T_1, T_2, the absolute temperatures at r_1 and r_2, r_1, the radius of the wire, r_2, the radius of wire + quenching radius for the *cyclo*propane/oxygen system[4], L, the wire length, and Q, the heat of reaction for *cyclo*propane/oxygen[5].

The mechanism of heat removal for the zone is a complex combination of conduction and convection. For the purpose of these calculations the heat removal is considered to be purely by conduction. This is permissible as ignition occurs before convection currents are set up.

$$q = \frac{km 2\pi L (t_1 - t_2)}{Ln \left(\frac{r_2}{r_1}\right)} \qquad (2)$$

where km is the thermal conductivity of the system[6], and t_1 and t_2 are the temperatures at r_1 and r_2.

Solving equations (1) and (2) graphically gives T_2 for a fixed T_1; T_2 can be obtained from a transient heat transfer solution for the system. Gemant[7] gives:

$$\theta = 1 + \frac{2}{\pi} \int_0^\infty e^{-(\tau\nu^2)} \cdot \frac{J_0(\rho\nu) N_0(\nu) - J_0(\nu) N_0(\rho\nu)}{J_0^2(\nu) + N_0^2(\nu)} \cdot \frac{d\nu}{\nu} \qquad (3)$$

where $\theta = T/T_0$ (T is the temperature difference between any point in the medium and the surroundings, and T_0, the temperature difference between the wire and the surroundings), and ν, the dimensionless variable extending from zero to infinity; $K = \frac{\tau a^2}{r}$, the thermal diffusivity of the medium; $\rho = r/a$ (dimensionless distance ratio); r, distance from centre of wire to point at temperature T; a, the wire radius; J_0, the Bessel function of first kind (zero order) and N_0, the Bessel function of second kind (zero order).

Fig. 1 shows a graphical solution of equations (1) and (2) for a stoichiometric *cyclo*propane/oxygen mixture at 3 atm. using a wire of diameter 1 mm. The solutions of equations (1) and (2) for wire diameters 1, 0·5 and 0·25 mm at 1 and 3 atm. are given in Table 1. It can be seen from Table 1 that for a fixed T_1, T_2 is independent of wire diameter. This enables a plot of log (T_1) versus log $(T_1 - T_2)$ (Fig. 2) to be made. This holds for any wire diameter and predicts for any T_1 the temperature at the quenching diameter required for ignition. The solution of equation (3) for wire diameters 1, 0·5 and 0·25 mm allowing a maximum[8] of 5 sec for an explosion to be initiated are given in Table 2. The mutual solutions of equations (1), (2) and (3) which enable the maximum permissible wire temperature for no ignition to be predicted are given in Table 3.

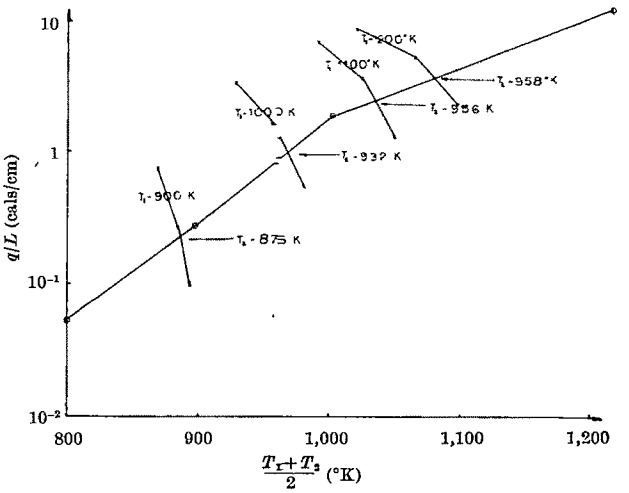

Fig. 1. q/L versus $\frac{T_1+T_2}{2}$ for stoichiometric *cyclo*propane/oxygen mixture at 3 atm. Diameter of wire, 1 mm

No reports are available for a direct comparison of these theoretically derived wire temperatures. However, Jones[9] has reported ignition temperatures of 450°–500° C for *cyclo*propane/oxygen mixtures in an evacuated bulb maintained at a predetermined temperature. These ignition conditions are similar to those that would be obtained using a thick heated wire ($\theta = 0{\cdot}99$). In the temperature range considered this corresponds to $T_1 - T_2 = 3°–5°$ C, which from equation (4) gives the wire temperature as 450°–500° C.

The experimental ignition temperatures obtained for the evacuated flask and the values predicted for a thick wire are in reasonable agreement. This suggests that the

Table 1

assumptions made in the theoretical derivations are reasonable.

This technique can be used to calculate the maximum safe temperatures for electrically heated wires in explosive atmospheres at pressures up to 3 atm.

The use of spark discharges in similar explosive atmospheres would have to be treated by a different analysis; however, in general, the energy dissipated in the type of sparks used in surgical practice is high enough to render the technique dangerous in oxygen atmospheres containing anaesthetic gases such as *cyclo*propane.

Absorption Spectra of Cadmium and Zinc Atoms trapped in Noble Gas Matrices

THE absorption spectra of cadmium and zinc atoms trapped in argon, krypton and xenon matrices at low temperatures have been observed in the region λλ 1600–3500 Å. Spectra were recorded for various matrix/impurity (M/A) ratios, and at several temperatures. This communication reports our preliminary results.

The experimental procedure used for the preparation of inert-gas films doped with metallic impurities was similar to that described elsewhere[1–3]. Metal atoms were vaporized from a stainless steel oven and allowed to mix with a beam of the noble gas at the liquid helium-cooled deposition window. This window was of lithium fluoride, calcium fluoride, or quartz. No difference was noticed in the absorption spectra when the samples were deposited on different substrates. The matrix gases were British Oxygen Company spectroscopically pure grade, while the cadmium and zinc metals were 99·999 per cent pure. Spectra were recorded photographically with Ilford $Q2$ plates on a 1 m normal incidence vacuum spectrograph having a dispersion of 16·7 Å/mm in the first order.

The general features of the absorption spectra are: (1) A strong triplet within a few per cent of the free-atom $^1S_0$–$^1P^o_1$ transition energy; (2) one or two sharp doublets to the short wave-length side of the triplet, and of comparable intensity to the triplet; (3) diffuse broad bands to the red of the triplet; (3) weak, diffuse single absorptions to either side of the triplet.

If one correlates the triplet absorption with the $^1S_0$–$^1P^o_1$ transition of the free atomic impurity, the shift of this transition is to higher energy in argon and krypton, and to lower energy in xenon. This feature broadens quickly as the impurity concentration is increased. For a 1 per cent solution of cadmium in argon the 'triplet' absorption is approximately 200 Å wide. It is evident that the rapid increase in width with increasing impurity concentration is due to trapping of the foreign atoms at a multiplicity of sites. As a film containing a large concentration of cadmium or zinc atoms is allowed to warm up, this feature sharpens considerably.

The doublet absorptions were also found to broaden as the impurity concentration was increased, but to a lesser extent, and doublet structure could generally be resolved. In heavily doped samples, a sharpening of these features occurred as the temperature increased.

The broad absorption bands to the red of the $^1S_0$–$^1P^o_1$ transition appeared at medium and high concentrations of impurities. In the spectra of the systems cadmium–argon and cadmium–krypton one of these bands shows vibrational structure. These bands are probably due to weakly bound molecules formed between atoms trapped at nearby sites.

The absorption features were observed to shift to longer wave-lengths as the temperature of the sample increased.

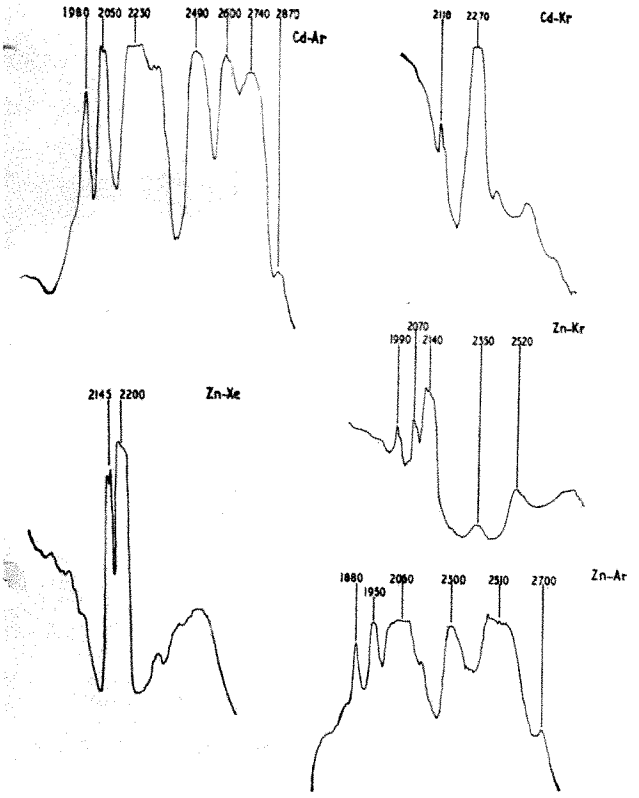

Fig. 1. Microdensitometer traces of the absorption spectra of zinc–argon ($M/A \simeq 100$), zinc–krypton ($M/A \simeq 300$), zinc–xenon ($M/A \simeq 200$), cadmium–argon ($M/A \simeq 100$) and cadmium–krypton ($M/A \simeq 1{,}000$) recorded at 4·2° K. Wave-lengths are in Å

The magnitude of this shift was similar to that reported for other systems[4–6]. At low impurity concentrations, when triplet structure was resolved, the components were observed to broaden considerably with increasing temperature.

Typical absorption spectra recorded at 4·2° K for the systems zinc–argon, zinc–krypton, zinc–xenon, cadmium–argon, and cadmium–krypton are shown in Fig. 1. A fuller description and interpretation of these results will be presented in a forthcoming publication.

I thank Prof. W. R. S. Garton and Dr. R. C. M. Learner for interesting discussions held during the course of this work. The support of the Athlone Fellowship Committee and the Canadian Defence Research Board is also gratefully acknowledged.

A Simple Micro-cuvette for Use in Standard Spectrophotometers

This apparatus was designed to enable optical density measurements to be made on very small volumes, using a standard spectrophotometer without further modification to the cell housing. A few small cuvettes are available commercially, but in these the advantages of small capacity are outweighed by short light paths. Several micro-cuvettes have been reported[1–3] but they are difficult to construct and require special techniques in handling[4]. The present apparatus is relatively simple in construction and use.

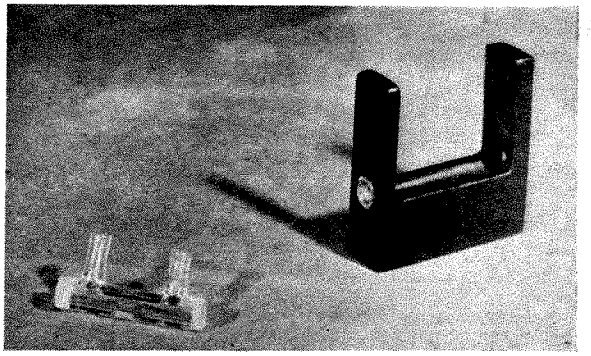

Fig. 1. Micro-cuvette and holder

The cuvette (Fig. 1) consists of a piece of thick-walled glass tubing of 3-mm bore, the ends of which are closed by disks of optically plane glass. These are cemented to the ends with 'Araldite' to avoid heat stresses or distortion which might be produced if they were fused. Two small side tubes are fitted, one at each end, and the cuvette is filled by means of a fine-bore Pasteur pipette placed inside one tube, the displaced air bubbling out of the other. After filling, minute air bubbles are dislodged by tilting towards each end in turn and gently tapping the sides.

A special holder (Fig. 1) has been designed for this cuvette for use with the Unicam '*S.P.* 500' spectrophotometer. This is made from a block of 'Darvic' (Imperial Chemical Industries, Ltd.) $1{\cdot}3 \times 4{\cdot}2 \times 4{\cdot}5$ cm which fits firmly inside the cuvette holder of the instrument. A 0·272 in. hole is bored lengthwise through the 'Darvic' block, the upper central portion of which is cut away leaving a semicircular trough in which the cuvette is placed. The remaining ends of the block help to keep it rigid in the metal cuvette holder and also serve as handles for inserting and removing the cuvette. The holes at either end of the trough are closed by brass plugs pierced by 0·086 in. holes, which are slightly smaller than the bore of the glass tube to eliminate stray light which might be refracted by the glass walls.

The cuvette has a light path of 3 cm and a total capacity of less than 0·3 ml. The universal cell housing of the instrument is used with the 12×2 mm shutter and cylindrical lens provided. Before readings are taken the cuvettes are allowed to equilibrate in the spectrophotometer for 10–20 min since small changes in temperature have a marked effect on the readings. It is essential for the light beam to pass accurately through the centre of the cuvettes so the spectrophotometer must be very carefully aligned. The carriage must be rigid in each of its set positions, and multiple readings should be taken to ensure it comes to rest in exactly the same position each time. It is necessary to match the cuvettes beforehand when filled with pure solvent and to subtract the small blank readings before calculation. Once matched, each cuvette should always be used the same way round in the same holder.

To test the reproducibility of readings in these cuvettes, two alcoholic solutions of gentian violet were measured in turn in two cuvettes. They were emptied and refilled twice and each time triplicate readings were taken. The results are shown in Table 1. Analysis of these data shows

Table 1. Optical Densities of Gentian Violet Solutions ($E \times 10^3$)

	Dilute solution		Concentrated solution	
	Cuvette 2	Cuvette 3	Cuvette 2	Cuvette 3
Read (1)	170, 172, 173	171, 172, 172	722, 722, 720	701, 701, 701
Refill (2)	174, 173, 174	174, 174, 175	722, 722, 727	721, 721, 721
Refill (3)	177, 175, 178	175, 174, 175	717, 722, 722	711, 711, 711
	Mean = 174 ± 2·0 *S.D.* Coefficient of variation = 1·2 per cent.		Mean = 716 ± 8·3 *S.D.* Coefficient of variation = 1·2 per cent.	

a coefficient of variation of 1·2 per cent for both a dilute and a concentrated solution.

This work was supported by a grant from the British Empire Cancer Campaign. I thank Mr. G. Marshall for skilful assistance in making the plastic holders and Mr. E. Roberts for the construction of the cuvettes.

Electrodialysing with a Non-polarizing Membrane

IN the electrodialysis process for demineralizing brackish water, the feed is passed through parallel compartments separated by cation- and anion-exchange membranes arranged alternately. A direct current passed at right-angles to the long, narrow compartments impels the cations and anions to pass through the appropriate, selective membranes, so that alternate compartments become either depleted or concentrated in dissolved salts.

It has been found that when a critical current density is exceeded, the transport of ions to the membrane surface is insufficient to maintain the current, and hydrogen and hydroxyl ions pass through the membrane instead, at a higher voltage[1]. The excess energy is dissipated by the splitting of water molecules. Moreover, the *p*H change caused by hydroxyl ions passing through the anion-exchange membranes induces scale to form in the concentrate compartments, further increasing the electrical resistance and eventually blocking the membranes. In practice, therefore, the current density is maintained at a value of only about 50 per cent of the theoretically critical one. Since the output from an installation is proportional to the current density, this is a serious limitation.

During a recent investigation[2], a series of commercial ion-exchange membranes were tested in the following cell:

Silver/silver chloride | 0·01 N sodium chloride | Membrane | 0·01 N sodium chloride | Silver/silver chloride

Each membrane was clamped horizontally and the current was so arranged that the flow of counter-ions was upward, minimizing convection. The change of voltage with time was noted for constant current.

Fig. 1 is a chronopotentiograph of 'Selemion *DMT*', a weak-base anion-exchange membrane manufactured for dialysis purposes[3]. When the solution layer immediately below the membrane became depleted of salt, the resistance rose and hydroxyl ions began to carry an increasing proportion of the current upwards, towards the cathode. Above *p*H 8–9, however, there was practically no dissociation of the weakly basic groups and the membrane became non-selective. Electrolyte replenished the depleted membrane-solution interface and permeated the membrane, the current being transported by both sodium and chloride ions. The electrical resistance fell accordingly, as did the *p*H, the functional groups increased their dissociation and the cycle continued. Eventually a steady-state would have been reached.

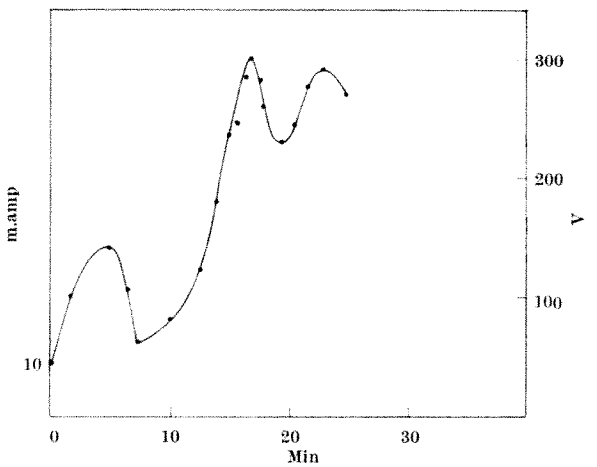

Fig. 1. Voltage-time curve for 'Selemion *DMT*'

Suppose such a membrane were used in electrodialysis. An increase in the current density above the critical value would not cause scale and stoppage of the process; instead, the current efficiency would simply decline locally until operating conditions were corrected. This could permit the operating current density to be raised much closer to the theoretically critical value. Only trials in a multi-membrane stack could test the validity of this approach.

Combined Ion Exchange–Solvent Extraction: a New Dimension in Inorganic Separation Chemistry

MOST of the methods at present used for separation of inorganic ions by column chromatography are either based on cation and anion exchange or on partitition chromatographic procedures using cellulose, silica gel, 'Kel-*F*' and various other inert materials as supports for a stationary phase, mostly an aqueous solution, or, as with the reversed-phase techniques, with an organic phase which either acts as an extractant or as a cation or anion exchanger. Common to these methods is the fact that only one mechanism (either ion exchange or solvent extraction) is the decisive factor for effecting the separation. This is especially so in relatively strong mineral acid solutions. Seen from this point of view, these separation techniques are in practically all cases only one-dimensional, that is to say, only one of these principles can be utilized.

Obviously a two-dimensional separation system can be obtained by combining the ion exchange principle with liquid–liquid extraction. This can be achieved by using a solid cation exchanger as the support and a partly non-aqueous system as the mobile phase acting as an extractant for certain metal ions. Consequently, separations which can be achieved under such conditions may be termed "combined ion exchange-solvent extraction" separations (CIESE) because both the principles of ion exchange and solvent extraction are operative simultaneously. The following two separations of large amounts of iron from cobalt and nickel and of uranium from other elements are examples of this CIESE principle.

In the first case, the separation of iron(III) is effected on a column of a 'Dowex 50' cation exchanger using 80 per cent (tetrahydrofuran) (THF)–20 per cent 3 N hydrochloric acid as the eluent. Under these conditions, iron (III) (distribution coefficient $K_d \simeq 1$) is removed by washing the resin with this mixture and cobalt is then eluted with 90 per cent THF–10 per cent 6 N hydrochloric acid (v/v) leaving nickel adsorbed on the column. The nickel can finally be eluted with pure aqueous 6 N hydrochloric acid. This separation cannot be achieved on the same resin using pure aqueous 0·6 N hydrochloric acid (same overall acidity as in the THF–hydrochloric acid mixtures) because the K_d-values are 180 (iron), 45 (cobalt),

and 45 (nickel). This is also impossible using the conventional extraction method for iron (III), that is, extraction from 6 N hydrochloric acid by means of ethers, ketones or esters, because this only removes the iron (III) from the aqueous phase leaving the cobalt and nickel unseparated.

In the second case, the separation of uranyl nitrate from practically all other elements is effected on the same resin using 90 per cent THF–10 per cent 6 N nitric acid (v/v) as eluent for the uranium (K_d value, 40). Under these conditions, the K_d values of practically all other elements including di-, tri- and higher valent ions are either $> 10^3$ or ~ 1 so that a very effective separation is obtained. This separation cannot be achieved if a pure aqueous solution in nitric acid of the same acidity is used. Following elution of uranium with the above THF–nitric acid mixture, fractionation of the adsorbed elements can be achieved using the THF–hydrochloric acid eluents as in the separation of iron (III), cobalt and nickel. A fractionation of this kind is not achieved by the common extraction methods for uranyl nitrate with ethers, esters, or ketones from aqueous nitric acid solutions containing nitrates as salting agents.

These two examples of the application of the CIESE principle demonstrate that it is superior both to common ion exchange in pure aqueous solution and to the conventional liquid–liquid extraction method for the removal of iron (III) chloride and uranyl nitrate.

The main advantages of the CIESE principle over the one-dimensional separation principle (conventional column chromatography and solvent extraction) are:

(1) After removal of one or more components as with liquid–liquid extraction a further fractionation of other elements on the solid exchange material is possible.

(2) No salting agents or high concentrations of strong acids are necessary so that subsequent separations can readily be achieved without interference by these agents.

(3) The main constituent which is preferentially eluted (in our case iron and uranium) may be present in gram quantities without affecting the separations.

As a result of these advantages, the CIESE principle is of great use, especially when trace or minor constituents have to be separated from the bulk of the sample and further fractionation of these minor constituents is necessary. The aforementioned two examples can thus be used for the analysis of ferrous materials, such as steel and iron meteorites, and for the separation and preparation of highly pure uranyl nitrate.

To explain this CIESE principle it can be assumed that THF reacts with the mineral acid present to form an oxonium salt which acts as a liquid anion exchanger and thus reacts with the anionic complexes of the metal ions present. Consequently this liquid anion exchanger competes with the solid cation exchanger for the metal ions and according to the experimental conditions either the solid or liquid exchanger retains them preferentially.

The effect of the liquid exchanger, that is, the 'extraction' effect, was found to increase both with increasing THF and mineral acid concentration. Similar effects can be observed in ketone and ether–alcohol media (such as methyl glycol) containing hydrochloric acid but not when these contain aliphatic alcohols.

The CIESE principle can probably also be used for many separation purposes other than those already mentioned by suitable choice of the liquid organic component, complexing acid and solid exchange material.

BIOCHEMISTRY

Identification and Estimation of (+)-Abscisin II ('Dormin') in Plant Extracts by Spectropolarimetry

ABSCISIN II is a recently discovered[1,2] plant hormone which appears to inhibit the action of auxins, gibberellins and kinins[3]. Its structure[4] (I) contains one centre of asymmetry, and a comparison of its properties with those of synthetic[5] (±)-abscisin II suggested that the natural substance is a single enantiomorph. We have now measured the optical rotatory dispersion of abscisin II from sycamore leaves[2], and find that the hormone from this source is dextro-rotatory and exhibits a very intense positive Cotton effect with extrema at 287 mμ ([α] + 24,000°) and 245 mμ ([α] −69,000°):

(I)

All measurements of optical rotatory dispersion were made in acidified methanolic or ethanolic solutions (c = 1–50 μg/ml., l = 1 cm). Although the ultra-violet absorption spectrum of abscisin II is sensitive[2] to pH, it was found that λ_{max} and ε_{max} reach constant values (262 mμ and 21,400, respectively) when the solution is ⩾ 0·002 N in sulphuric or hydrochloric acid; the absorbance of such solutions can then be used to measure abscisin concentrations. The position and amplitude of the Cotton effect also become constant when the solution is ⩾ 0·002 N in acid.

The exceptionally high amplitude of the Cotton effect (corresponding to a swing of 250,000° in molecular rotation) and the availability of a sensitive spectropolarimeter (a Bellingham–Stanley 'Polarmatic 62') provide a method for detecting and estimating (+)-abscisin II in plant extracts. The limit of detection for the pure compound is 0·5 μg in the 0·65 ml. of solvent required to fill the polarimeter cell (a sensitivity similar to that of our bioassay[2] using excised wheat embryos). In the presence of other light-absorbing substances the performance of the polarimeter falls with decreasing light transmission by the solution, and crude plant extracts required cleaning-up before satisfactory measurements of optical rotatory dispersion could be made. Usually, isolation of the ether-soluble acidic components and their separation by thin-layer chromatography (kieselgel-G; propanol–butanol–ammonia–water, 6 : 2 : 1 : 2 v/v) sufficed. A Cotton effect of the correct shape and position, and inhibitory activity measured by bioassay[2], both confined to material at the same R_F (about 0·65) as that of a reference marker of (±)-abscisin II, were taken as positive identification of (+)-abscisin II, while the intensity of the Cotton effect provided a measure of the concentration which could be checked against the inhibitory activity. Because the optical rotation of (+)-abscisin II is so large, interference from other substances was negligible; for example, material eluted from other areas of the thin-layer plates showed no measurable rotation under conditions suitable for detecting (+)-abscisin II.

We have used the method described here to detect (+)-abscisin II in the following:

Species	Organ	Date of harvest
Sycamore (*Acer pseudoplatanus*)	Buds; debudded twigs (cf. leaves (ref. 2))	January 19, 1966
Birch (*Betula pubescens*)	Leaves	November 12, 1964
Rose (*Rosa arvensis*)	Achenes; pseudocarp	December 13, 1965
Cabbage (*Brassica oleracea*, hort. var.)	Leaves of the heart	December 13, 1965
Potato (*Solanum tuberosum*)	Tuber	November 10, 1965
Avocado (*Persea grantissima*)	Seed	—
Lemon (*Citrus medica*)	Fruit	—

Through the courtesy of Mr. H. W. B. Barlow of the East Malling Research Station we have also been able to examine an extensively purified inhibitor from plum twigs[6] (*Prunus domestica*, var. 'Myrobalan B'), and have identified the major component as (+)-abscisin II (ultra-violet and infra-red spectra, chromatographic behaviour, and optical rotatory dispersion).

The concentration of (+)-abscisin II found in the plant tissues examined has been of the order of one part in ten million, fresh weight.

Evidence is accumulating that (+)-abscisin II can account for most of the inhibitory activity found in the acid fraction of plant extracts[7]. However, its physiological function is still incompletely defined and would seem to be as complex as that of the other plant hormones. Abscisin II has already been implicated in abscission in cotton[1] and in dormancy in sycamore and birch[8]. It may also be one of the natural germination inhibitors in the rose studied by Jackson[9], because we find large quantities in the pseudocarp of rose hips and smaller amounts in the achenes.

We thank Mrs. P. Gajdatsy and Mr. D. T. Green for help with the extractions and measurements of optical rotatory dispersion respectively.

Production of Cysteic Acid, Taurine and Cystamine under Primitive Earth Conditions

IT is now well established that most of the simple, biologically-important 'monomers' (such as amino-acids, pentoses, purines and fatty acids) are formed when various high-energy sources are applied to samples of the atmosphere of the primitive Earth[1-2]. This atmosphere is assumed to consist mainly of methane, water, ammonia, nitrogen and hydrogen (the last decreasing rapidly with increased age of the Earth)[3]. Although the amino-acids are among the most prominent products of the irradiations of 'primitive-Earth atmospheres', no report has yet appeared in the literature of the appearance of the sulphur-containing amino-acids. This has presented no problem, since it can safely be assumed that the primitive atmosphere contained at least traces of hydrogen sulphide—however, it is important to have laboratory experimentation to back up assumptions.

Primitive Earth atmospheres, in the presence of added hydrogen sulphide, have been studied by Heyns, Walter and Meyer[4]. These authors passed a spark through the mixture and found essentially that the hydrogen sulphide had no effect on the syntheses of non-sulphur-containing amino-acids. They tentatively identified one sulphur-containing product, ammonium thiocyanate. However, a search for sulphur-containing amino-acids (by the method of Stein and Moore[5]) was unsuccessful, although the authors did report the presence on their chromatograms of six ninhydrin-positive, but unidentified, products. These amino-acids may have been sulphur-containing, but their yield was too small to permit identification.

It seemed to us to be worthwhile to search for the 'primitive Earth' synthesis of sulphur-containing amino-acids by using $H_2{}^{35}S$ as one of the reactants, thus greatly increasing the detection sensitivity for an amino-acid product. In this way we have been able to establish the appearance of cysteic acid ($HO_3SCH_2CH(NH_2)CO_2H$) and the closely related compounds taurine ($HO_3SCH_2CH_2NH_2$) and cystamine ($SCH_2CH_2NH_2)_2$. Cysteine and cystine probably were formed (there was evidence for them in our early chromatograms), but they appeared to be oxidized to cysteic acid during subsequent chromatography. We found no evidence for methionine production.

In each of the three experiments reported here, 20 ml. of 2 N ammonium hydroxide, 200 mm of methane and 100 mm of $H_2{}^{35}S$ (containing 5 mc.) were placed in a 'Pyrex' tube and irradiated, with an electron beam, in the manner previously described[6]. No air was present during the irradiations. The electron beam was used for no reason other than that it was a convenient source of ionizing radiation. The radiation dose in each case was about 10^9 rads. This is a very high dose; however, our products, as they were formed, were removed from the electron beam (in the condensate dripping off a condenser—see ref. 6) and thus protected from radiation decomposition. The 10^9 rads were delivered during 45-min exposures to the electron beam.

After the addition of chromatographic quantities of unlabelled carriers (cystine, taurine, etc.), the non-volatile contents and washings from the irradiation chamber were transferred to a round-bottom flask and evaporated to a small volume at room temperature. Centrifugation was then employed to remove some polymeric material (in part, elementary sulphur). An aliquot portion (usually 0·1) of the concentrated solution was then placed on Whatman No. 1 chromatographic paper. The solvent in the first direction was *n*-butanol–acetic acid–water (100 : 22 : 50, v/v/v) and, in the second, isopropanol–methanol–water (7 : 1 : 2, v/v/v). The positions and shapes of radioactive spots were determined by autoradiography (Kodak 'Blue Sensitive' medical X-ray film). Radioactive spots with R_F values similar to those of added carrier compounds were cut out, eluted and rechromatographed in the following solvent systems: (1) secondary butanol–formic acid (88–90 per cent)–water (15 : 3 : 2, v/v/v); (2) secondary butanol–tertiary butanol–water (43 : 48·4 : 8·6, v/v/v). On the second chromatograms the positions and shapes of the radioactive spots were compared with those of the coloured spots revealed by spraying the chromatogram with ninhydrin solution. The amount of radioactivity in a given spot was determined either (1) directly on the paper by means of a Geiger–Müller counter or (2) after elution, by liquid scintillation counting. This radioactivity figure could then be compared with the total amount of ^{35}S (as $H_2{}^{35}S$) that was originally present in the irradiation flask. In this way, the yields of products from the hydrogen sulphide could be determined (due allowance being made for the half-life of ^{35}S).

The following ^{35}S-labelled products (yield from $H_2{}^{35}S$ given in parentheses) were positively identified: cysteic acid (0·01 per cent), cystamine (0·003 per cent), and taurine (0·01 per cent). We expected to find, and therefore intensively searched for, cysteine, cystine, and methionine; however, if these amino-acids are formed, their yields must be well below 0·001 per cent. As was mentioned, cysteine and cystine are probably formed but then disappear by oxidation to cysteic acid. Other compounds for which we searched were homocysteine and homocysteic acid, but we could find no evidence for their synthesis.

It is pleasing to record that at least one of the sulphur-containing α-amino-acids (cysteic acid) is formed under 'primitive Earth conditions'. We believe that others

are also formed (for example, the cysteic acid is probably formed by attack of the ·OH radical on cysteine). Probably, small changes in the conditions of the 'primitive Earth' experiments (such as longer times of irradiation at lower dose rates, presence of catalytic surfaces) will lead to the identifications of all the biologically important sulphur-containing amino-acids.

This work was sponsored in part by the United States Atomic Energy Commission. It was carried out during the tenure (1964–65) of an International Atomic Energy Postdoctoral Fellowship.

Inhibition of 6-Methylsalicylic Acid Synthesis in *Penicillium patulum*

VARIOUS reports[1–3] have indicated that the biosynthesis of 6-methylsalicylic acid (2,6-cresotic acid; 6-MSA) may be patterned after fatty acids, involving the condensation of one acetyl and three malonyl derivatives (presumably derivatives of coenzyme *A* or of a protein analogous to the acyl carrier protein[4] in *E. coli*). Bu'Lock and Ryan[5] and later Tanenbaum and Bassett[6] showed that 6-MSA is metabolized by *Penicillium patulum* to form patulin and possibly other compounds as well. These compounds, which have been designated secondary metabolites[7], have no apparent function in the organism. While the formation of 6-MSA is limited to a few species, the phenomenon of secondary metabolite formation is widespread in micro-organisms.

Factors governing the appearance and metabolism of secondary metabolites are still obscure, although some evidence indicates the nutritional environment of the cells is very important[7,8]. Bu'Lock and Powell[7] have distinguished between a 'tropophase' or balanced phase of growth and an 'idiophase' (peculiar phase) of growth marked by carbon assimilation and secondary metabolite production in *P. patulum*. They briefly referred to an inhibition of 6-MSA synthesis by 6-MSA. This communication reports experiments indicating such an inhibition not only by 6-MSA, but also by structural analogues of this compound.

Spores of *P. patulum* (NRRL 2159A) were washed from Czapek-Dox agar slants and added to 50-ml. Erlenmeyer flasks containing 20 ml. of Czapek-Dox medium. (Czapek-Dox medium contained 50 g glucose, 2·0 g sodium nitrate, 1·0 g potassium dihydrogen phosphate, 0·5 g potassium chloride, 0·37 g magnesium sulphate (dried powder, 65·6 per cent magnesium sulphate), 0·01 g $FeSO_4 \cdot 7H_2O$, in 1 l. distilled water. Slants contained 1·5 per cent agar in addition.) The inoculum usually contained about 5×10^6 spores per flask.

After an appropriate period of growth at room temperature (25° C), 8 μc. of 1-^{14}C-sodium acetate (50 mc./mmole) was added, and 10-μl. portions of the growth medium were spotted at timed intervals on thin-layer plates[9] coated with 'Adsorbosil'. Carrier 6-MSA was added to the spots, plates were developed in hexane–ether–acetic acid, 80 : 15 : 2, and the 6-MSA spots were detected by blue fluorescence under ultra-violet. The silica gel from each spot was transferred to a scintillator bottle along with 'Cab-o-sil' and toluene scintillator solution (4 g 2,5-diphenyloxazole, 0·05 g 1,4-*bis*-2-(5-phenyloxazolyl)-benzene, 1 l. toluene) and assayed for radioactivity in a Packard 'Tri-Carb' liquid scintillation counter. The method of Lands and Hart[10], in which plates are sprayed with 'Neatan', was helpful in transferring the adsorbent.

It was difficult to obtain a definite criterion for the age and condition of culture flasks which would give the best rate and extent of incorporation since germination time and growth rate varied from one experiment to the next. We generally used cultures in which the synthesis of patulin had begun, when the optical density of a 1:100 dilution of the growth medium reached 0·1 at 276 mμ (ε reported 13,350[11]; found 14,900). Results should be compared only with controls in the same experiment.

The rate of incorporation of 1-^{14}C-acetate into 6-MSA was decreased in the presence of added 6-MSA, as shown in Table 1. The concentration of 6-MSA normally found in the culture medium at this time was between 0·1–0·5 μmoles/ml. as estimated by visual comparison with standards of thin-layer plates after exposure to iodine vapour. Values obtained by extraction of the acidified growth medium with ether, chromatography of the extracts on silicic acid, and measurement of the absorption at 310 mμ[11] also fell within this range. The concentration at which inhibition was observed was thus only slightly greater than that already present, suggesting that the inhibition could be a factor in controlling 6-MSA metabolism.

Table 1. INHIBITION OF 6-MSA SYNTHESIS BY 6-MSA

Cultures were grown for 7 days at room temperature before addition of 1-^{14}C-acetate. 10-μl. samples were assayed at various times as described in the text. Numbers in the table refer to radioactivity incorporated into 6-MSA 30 min after addition of acetate. This time was chosen to best reflect the initial rate of incorporation. Duplicate experiments are given.

Addition of 6-MSA* (μmoles/flask)	^{14}C in 6-MSA (c.p.m./10 μl) Exp. 1	Exp. 2
None	195	195
33	85	45
80	10	10
132	5	5

* *p*H of 6-MSA solution was adjusted to 4·2 in order to prevent changing the *p*H of the cultures.

Structural analogues of 6-MSA also show a similar inhibition. Table 2 describes similar experiments with phenol, benzoic acid, and salicylic acid.

Table 2. INHIBITION OF 6-MSA BY STRUCTURAL ANALOGUES

Conditions were similar to those for Table 1 except for the age of cultures when acetate was added. In experiment No. 3, flasks were grown 8 days; in experiment No. 4, 10 days; and in experiments Nos. 5 and 6, 6 days.

Additions (μmoles/flask)	^{14}C in 6-MSA after 30 min (c.p.m./10 μl) Exp. 3	Exp. 4	Exp. 5	Exp. 6
None	85	85	109	150
Phenol (212)	45	35	—	—
Benzoic acid (164)	35	5	—	—
Salicylic acid (145)	—	—	5	5

It should be emphasized that it is the rate of incorporation of acetate into 6-MSA which is being inhibited, and it is not clear whether a specific step of 6-MSA synthesis or some more general metabolic process is being affected. It would be premature to classify this as a general feed back inhibition until an effect can be demonstrated on an isolated enzyme in the pathway of 6-MSA synthesis. A repression of enzyme synthesis should be ruled out because the inhibition is seen immediately after addition of 6-MSA.

The possibility that 6-MSA and salicylic acid were inhibiting by binding some essential metal ion was tested by investigating the effect of EDTA, which is a considerably stronger metal complexing agent than salicylic acid[12]. EDTA may have a slight inhibitory effect on the rate of incorporation as indicated in Table 3, but the effect is not so great as with 6-MSA and salicylic acid at equivalent

concentrations. Another effect, however, was noticed with EDTA that was not seen with the other compounds investigated. The total incorporation of radioactivity into 6-MSA at longer times after acetate addition was increased by EDTA.

Table 3. EFFECT OF EDTA ON 6-MSA SYNTHESIS

Conditions were similar to those for Tables 1 and 2. Data were obtained in same set of flasks as experiments Nos. 3 and 4, Table 2, and experiments are numbered accordingly. Incorporation into patulin is also shown.

Experiment	Additions (μmole/flask)	^{14}C in 6-MSA Time after acetate addition: (min) 20	60	180	300	^{14}C in patulin 90 h
		c.p.m./10 μl.				c.p.m./10 μl.
3	none	65	130	100	110	150
	EDTA (132)	55	125	165	190	475
4	none	70	105	95	100	200
	EDTA (132)	36	80	170	295	530

Such an effect could be explained by an inhibition of a competing pathway of acetate metabolism making labelled acetate available for a longer period of time. An inhibition of the further metabolism of 6-MSA could also explain the phenomenon; however, incorporation of acetate into patulin, one of the known products of 6-MSA, was also increased by EDTA. Patulin was assayed in a similar manner to 6-MSA by developing the plates in ether–hexane. 75 : 25, and locating spots by a brief exposure to iodine vapour. Normally, radioactivity began to appear in patulin about the time it began to disappear from the 6-MSA fraction (usually 10–30 h after addition of labelled acetate), which would be expected from their presumed precursor-product relationship.

If the biosynthetic pathways of 6-MSA and fatty acids are similar, it should be of interest to determine whether 6-MSA also inhibits fatty acid synthesis.

Antagonism between Alloxan and Caffeine

IT has been reported[1] that mice with the hereditary obese hyperglycaemic syndrome react paradoxically to alloxan administration. (The obese hyperglycaemic syndrome entails, *inter alia*, extreme adiposity (with weight up to 120 g instead of about 30 g in non-obese littermates), pancreatic islets hyperplasia, moderate hyperphagia, extreme inactivity, a high blood glucose (generally 250–450 mg per 100 c.c.) despite high pancreatic and circulating insulin-like activity, insulin resistance and extreme sensitivity to cold[2]. The adipose tissue of animals with this syndrome shows a number of metabolic idiosyncrasies, in particular, enormously increased capacity for lipogenesis despite decreased glucose uptake[3] and an absence of increase in fat mobilization by epinephrine or FMS[4]. It appears likely that the primary inborn error is the lack of the normally present repressor to glycerokinase in the white adipose tissue[5] with the pancreatic hyperplasia, hyperinsulinism, increased hepatic lipogenesis, etc., secondary. Contrary to what could be expected on the basis of countless experiments by many investigators working with alloxan in many species, administration of a dose of alloxan which is diabetogenic to the non-obese littermates (or of twice that dose) causes a marked decrease in blood glucose lasting many months and a massive regranulation of the otherwise completely degranulated hyperplastic beta cell tissue of the islets of Langerhans[1].

This finding led us to investigate in this syndrome the action of substances related chemically to alloxan (purines, pyrimidines and an alkaloid, that is, uric acid, lactim and lactam forms, adenine, cytosine, guanine, hypoxanthine, uracil, thymine, xanthine and caffeine). Of these, only caffeine has a marked and reproducible effect[6]. The sensitivity of obese hyperglycaemic mice to the toxic effects of caffeine is extreme; while the LD_{50} is 10 mg per animal for lean littermates (500 mg per kg of body-weight), it is only 3·5 mg per animal for the obese hyperglycaemic (80 mg per kg of body-weight). While a 24-h or 48-h fast increases tolerance to alloxan, it increases the toxicity of caffeine. The effect of caffeine on blood glucose-levels of obese hyperglycaemic mice is remarkable. While in non-obese animals after an injection of 5 mg of caffeine (not lethal in any animal) the blood glucose (determined by the Nelson–Somogyi method[7]) shows a transient 60 per cent fall but goes back to normal within 24 h and stays normal thereafter, in obese mice a dose of 2 mg of caffeine (30 per cent lethal) causes the blood glucose-level to rise from 300 mg per 100 c.c. to nearly 500 mg in 6 h, 540 mg in 12 h, and more than 600 mg on the average after 4 days, with the blood glucose staying above 500 mg per 100 c.c. for several months. In fact, so sensitive are the obese hyperglycaemic mice to the action of caffeine that it is enough to replace their drinking water by instant coffee for a week to elevate their blood glucose for 75 days[6].

The mechanism of this effect is as mysterious as that of alloxan. Histological investigations and the use of carbon-14-labelled caffeine have so far given us no clue to the mode of action of this substance. The striking contrast between the actions of these two substances suggested that an examination of the effect of simultaneous injection in obese hyperglycaemic mice and in normal mice would be useful. This preliminary report indicates that caffeine and alloxan are direct antagonists. Among a number of experiments demonstrating this antagonism, the following are typical.

When alloxan was injected intraperitoneally, in saline, with dextrose solution available for 30 h, to groups of six to ten animals, a dose of 5 mg caused the blood glucose of lean mice to rise in two weeks from an average of 115 mg per cent to an average of 205; that of 7·5 mg alloxan from 115 to 470; that of 10 mg was almost uniformly lethal; the blood glucose of obese hyperglycaemic mice was reduced by 5 mg of alloxan from 450 to 180 mg per 100 c.c. in 10 days, then climbed back to 400 mg per 100 c.c. by the end of 2 weeks; after injection of a dose of 7·5 mg, the blood glucose went down on the average from 500 to 350 mg per 100 c.c. in the 2 week period; after injection of a dose of 10 mg, the average blood glucose went down from 420 to 175 mg per 100 c.c. in 2 weeks, having touched a minimum of 120 mg per 100 c.c. after 1 week. Again, as expected from previous experiments, the intraperitoneal administration of a single dose of 2 mg of caffeine to obese mice causes a rise in blood glucose from 350 to 500 mg per 100 c.c. during the course of the next 4 days, the blood glucose reaching 450 mg per 100 c.c. after 2 weeks; the blood glucose of lean mice is essentially unaffected after administration of 5 mg of caffeine.

In non-obese mice, the simultaneous administration of 5 mg of caffeine neutralized the effect on blood glucose of 5 mg of alloxan, with the blood glucose only temporarily rising from 120 to 140 mg per 100 c.c.; again, with 5 mg

of caffeine injected at the same time, the administration of 7·5 mg alloxan held the temporary rise in blood glucose to 25 mg per 100 c.c. or less. When 10 mg of alloxan was given, the simultaneous administration of the same dose of caffeine reduced the mortality from 100 to 30 per cent and again eliminated temporary (or even transient) diabetes. The action of the two substances on the histology of the pancreas (fixation in Bouin's solution with mercuric chloride stain with aldehyde thionin stain) also shows the antagonism observed with blood glucose: granulation of the beta cells of the islets of Langerhans, which is classically eliminated after administration of alloxan, was preserved when caffeine was injected simultaneously. In obese hyperglycaemic mice, a dose of 2 mg of caffeine neutralized (except for a temporary drop) the blood glucose lowering effect of 5 or 7·5 mg alloxan. When 10 mg of alloxan was injected at the same time as 2 mg of caffeine, the drop in blood glucose was about half what it was without caffeine (from 470 to 230 mg per 100 c.c. after 10 days; 285 mg per 100 c.c. after 2 weeks). The action of alloxan in causing the appearance of granulation in the otherwise degranulated beta cells of the islets of obese hyperglycaemic mice was decreased in varying degree by caffeine.

The close relationship between the chemical formulae of caffeine and alloxan (which led to the examination of the effect of caffeine in the first place), and the fact that the antagonism as regards blood glucose and histological appearance of the pancreas is seen in two situations where the actions of the two drugs are entirely reversed, make it likely that both compounds are acting on the same beta cell structures as true chemical antagonists.

This work was supported in part by a grant-in-aid from the U.S. Public Health Service, National Institutes of Health, and by the Fund for Research and Teaching of the Department of Nutrition of the Harvard School of Public Health. Quantitative Determination of Purine Derivatives in the Presence of Denatured Protein

RECENTLY Currie[1] reported the strong adsorption of purine bases on precipitated protein. In spite of repeated washings with 8 per cent perchloric acid, only 30–40 per cent of the added quantity of xanthine, hypoxanthine and uric acid was recovered. The determination of the bases was carried out enzymatically with xanthine oxidase. As perchloric acid is at present being used as the standard method for deproteinization much of the work concerning the metabolism of purine derivatives would, as a result, be incorrect[2–4].

We have, therefore, deproteinized rabbit kidney and liver tissue with 0·4 N perchloric acid; the tissues were rapidly chilled in liquid air after dissection. Solutions of hypoxanthine, xanthine and adenine were added and the concentrations of these substances were determined by ion exchange. Hypoxanthine and xanthine can be separated by anion exchange ('Dowex 1, *X*4', 200–400 mesh, Cl^-) using a solution of sodium tetraborate (*p*H 8·0; 0·1 N Cl^-) as the elution solvent. In addition, hypoxanthine can be determined alone on a cation exchanger ('Dowex 50*W*, *X*4', 400 mesh, Na^+) using a buffer of ammonium formate (*p*H 3·0; 0·05 N Na^+). With the same resin 1-methyladenine, adenine and 6-aminopurine (ammonium formate buffer *p*H 5·5; 0·35 N Na^+) can be separated[5].

Table 1. DEPROTEINIZATION WITH 0·4 N PERCHLORIC ACID AND WITH THE ADDITION OF DIFFERENT PURINE BASES

Substance	Substance/fresh weight in μmol/g	Tissue	Extractions with 0·4 N perchloric acid	Quantity of substance recovered (per cent)
Hypoxanthine	2·1	kidney	—	98·6
Hypoxanthine	2·1	liver	—	85·7
Hypoxanthine	2·1	liver	2	100·5
Hypoxanthine	0·074–0·15	liver	2	102
Xanthine	0·66	liver	2	101
Adenine	1·6	liver	2	108

We recovered 98 per cent of the added hypoxanthine in kidney tissue without additional extractions. Even smaller amounts (0·1 μmol/g fresh weight) were completely recovered. The adenine contents were not corrected against the control values, which probably resulted in excessive yields. A quantitative determination of the methylated adenine derivatives was dispensed with.

It was not possible to confirm by the foregoing experiments that by deproteinization with perchloric acid a loss of 60–70 per cent of the purine bases occurs due to adsorption on protein. All bases added were recovered quantitatively. Probably the experiments of Currie are explained by the inhibition of xanthine oxidase by traces of potassium perchlorate[6]. Apparently lithium perchlorate has no effect on the enzyme.

Control of Nicotinamide-adenine Dinucleotide Phosphate Synthesis in the Livers of Rats treated with Ethionine

INJECTION of tryptophan, nicotinic acid or, particularly, nicotinamide leads to high hepatic levels of NAD but very little increase in the hepatic NADP content[1–3]. This suggests that at super-normal levels of NAD factors other than NAD may be rate-limiting in NADP synthesis. NADP synthesis is a single-step reaction requiring only three components: two substrates, NAD and ATP, and one supernatant enzyme, NAD^+-kinase (*E.C.* 2.7.1.23). Using the observation of Shull[4] that ethionine injection causes a drastic fall in the hepatic ATP concentration *in vivo*, Greenbaum, Clark and McLean[5] studied the effect of a lowered ATP concentration on the synthesis of NAD and NADP 5 h after ethionine was injected. They found that neither the enzyme synthesizing NAD (NMN adenylyl transferase, *E.C.* 2.7.7.1) nor the enzyme forming NADP (NAD^+-kinase) was affected at this particular time. However, while NAD fell only slightly, NADP was reduced to about 60 per cent of the control value. It was suggested that ATP was involved in the control of NADP synthesis.

It seemed of interest to determine how the nucleotides varied hour by hour for the first few hours after injections since Shull[4] has shown that the hepatic ATP-level falls

to about 20 per cent of the control value 2–3 h after ethionine injection. Accordingly, female albino rats, of initial body-weight 200 g, were starved overnight and injected intraperitoneally with an aqueous solution of ethionine (500 mg/kg body-weight). They were killed by cervical dislocation at hourly intervals for the first 7 h after the injection and the nicotinamide nucleotides were extracted and assayed by the method of Greenbaum, Clark and McLean[6].

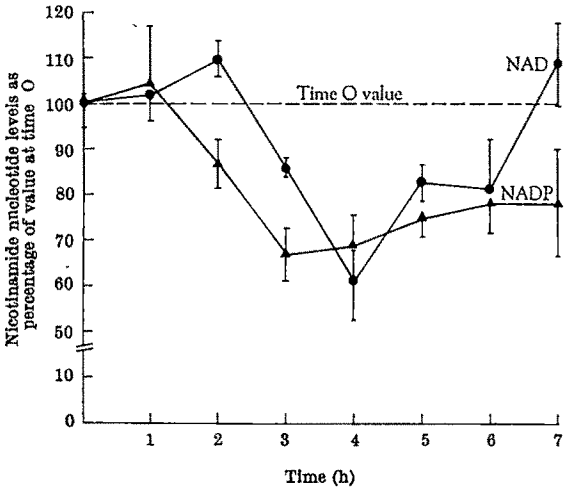

Fig. 1. Time course of the effect of ethionine on the NAD and NADP content of rat liver. The rats were given 100 mg of L-ethionine by intraperitoneal injection. They were killed at hourly intervals starting at 1 h and finishing at 7 h after injection. The oxidized and reduced forms of the nicotinamide nucleotides were extracted in 0·1 N hydrochloric acid and 0·1 N sodium hydroxide, respectively, and all four nucleotides estimated separately by the method of Greenbaum, Clark and McLean (ref. 6). The results are expressed as percentages of time O values calculated from the μg of nucleotide (oxidized plus reduced) per total liver. The vertical bars represent twice the *S.E.M* and each point represents the average of four rats. The values at time O for NAD were 3,561 ± 184 μg/total liver and for NADP, 1,564 ± 34 μg/total liver

The results are shown in Fig. 1 as the combined NAD^+ and NADH and $NADP^+$ and NADPH values expressed as a percentage of the time O values, since it is the total amount of nucleotide with which these experiments are concerned. Also they are calculated on the total liver basis since this is probably the most significant in relation to the whole animal.

The initial small increases in the nicotinamide nucleotides found in the first hour or so seem to be caused by the injection procedure rather than the ethionine since control animals injected with a similar amount of water showed the same trend (unpublished observations). This is contrary to the work of Yasin and Bergel[7], who reported little change (a slight loss if anything) in hepatic NAD after injecting water into rats. The hepatic NAD content starts to decrease after 2 h and reaches a minimum at 4 h, the level being about 60 per cent of the value at time O. After this the NAD content returns to the original values and at 7 h is, in fact, slightly higher than it was at 2 h. The NADP content of the liver starts to fall slightly earlier than the NAD, that is, after about 1 h and it reaches a minimum of about 65 per cent of the time O value at 3 h. Over the next 4 h it increases only slightly, some 10 per cent of the time O value, so that by 7 h NADP has not returned to the original values in the same way as NAD. Thus both NAD and NADP fall but only NAD returns to its normal level within the time span under consideration.

For the purposes of these results NADP synthesis should be considered in terms of the available NAD and ATP since the NAD^+-kinase shows no change 5 h after ethionine injection[5]. At 4 h when both NAD and NADP are at the respective minimal values, the ATP concentration of the liver is about 20 per cent of the normal value[4]. Thus a situation exists in the latter half of the time course when there is competition for the available ATP, and under these conditions NAD synthesis can proceed much faster relatively than NADP synthesis, leading to the normal values of NAD but still depressed values of NADP found at 7 h. It has been suggested that this greater facility for NAD synthesis rather than NADP synthesis in conditions of ATP (adenine moiety) limitation may be due to difference in the K_m for ATP of the enzymes involved in NAD and NADP synthesis and/or to the different intracellular localizations of these enzymes and the available ATP (ref. 5). Several workers[4,8,9] have attributed the effects of ethionine on cellular metabolism to its formation of *S*-adenosyl ethionine by means of the methionine activating enzyme (methionine adenosyl transferase. *E.C.*2.4.2.13). In this way ethionine causes an 'adenine' limitation in the cell. It is interesting, therefore, to note that Cantoni[10] has reported that the methionine activating system is present in the soluble fraction of the cell. Thus it may be suggested that the nuclear 'adenine' limitation is less severe than that of the cytoplasm, leading to the differential effects of NAD and NADP synthesis.

The observation of Dietrich and Yero[11] that, concomitant with the formation of high NAD-levels on nicotinamide injection, the hepatic ATP-level declines, also bears on the foregoing results and in addition on the observations of several workers[1–3] that nicotinamide injection causes high NAD-levels with very little corresponding rise in NADP. In both situations there is a limitation of available ATP leading to a priority system which allows NAD synthesis but not NADP synthesis. It is suggested also that at supernormal NAD-levels ATP will be the rate-limiting factor in NADP synthesis. However, in the first half of the time course a relationship seems to exist between NADP and the other substrate of NADP synthesis, NAD. Both NAD and NADP decrease in parallel and to levels approximately 2/3 of their time O values, although there is a time lag between their falls. This result is interesting in the light of the observations of Clark, Greenbaum and McLean[12] that in precancerous liver and hepatomas a similar relationship between NAD and NADP is apparent at normal and low NAD-levels. Investigations are continuing to establish more clearly the factors involved in the control of nicotinamide nucleotide synthesis and their relationship to overall metabolic control.

We thank Prof. A. L. Greenbaum for advice and criticism and the Medical Research Council for a research grant to one of us (J. B. C.).

Inhibitory Action of Glucides on Trypsin Activity

GLUCIDES, usually unimportant reagents, can affect the activity of enzymes. Farber and Wynne[1] have reported that some monosaccharides have marked inhibitory effect on the activity of pancreatic proteinase. A similar observation has been made by Whitaker *et al.*[2] with α-amylase. This report is concerned with the inhibitory effect of some mono- and di-saccharides on the activity of trypsin.

Trypsin activity was determined with azocasein substrate, prepared according to Charney and Tomarelli[3]. The trypsin (Merck) was used in 0·1 M phosphate buffer (*p*H 7·5). Glucides were dissolved in the enzyme solution. The reaction mixture, which contained 12·5 mg/ml. azocasein, 1 mg/ml. trypsin, and 1 M (in some cases 0·5 M) glucide, was kept 10 min at 40° C. After precipitating the non-digested proteins with trichloroacetic acid (final concentration 3 per cent), and mixing the filtrate with N sodium hydroxide, the extinction was obtained by means of a Pulfrich photometer with filter *S* 42, using for comparison blanks formed in the same way but without incubation. Trypsin activity was expressed as a percentage of the activity without glucides.

The effect of different concentrations of glucose was first determined (Fig. 1). It may be observed that the inhibitory effect runs parallel with the concentration of glucose. In order to compare the inhibitory effect of different glucides, the following were tested in 1 M concentration: D-arabinose, D-glucose, D-galactose, D-mannose, D-fructose, maltose and saccharose. The two disaccharides were also tested in 0·5 M concentration (Table 1).

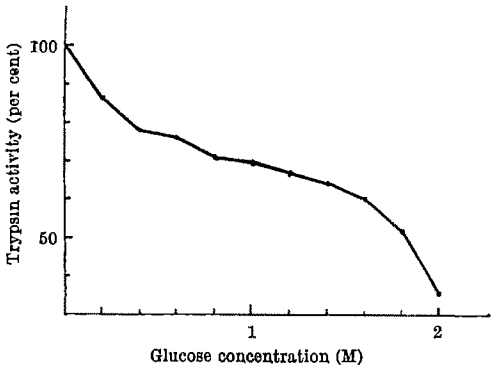

Fig. 1. Change of activity of trypsin with glucose concentration. Incubation time, 10 min; concentration of trypsin 1 mg/ml.; concentration of substrate (azocasein) 12·5 mg/ml. at *p*H 7 5 (in 0 1 M phosphate buffer). Rate of hydrolysis measured photometrically

The strongest inhibitory effect is shown by galactose. In general, except for galactose and arabinose, the inhibitory effect seems to follow the size of the glucidic molecules. These exceptions, as well as the remarkable differences noted in the behaviour of hexoses, suggest, however, that the spatial configuration of the sugars also plays a part in this inhibitory effect. There is no correlation between the inhibitory effect and the solubility of sugars.

The inhibitory effect is principally due to the steric inhibition of the enzymatic reactions, and evidently differs from the well-known substrate inhibition. The glucidic molecules mechanically isolate those of the enzyme and substrate from each other. No doubt, however, the increase of viscosity caused by the sugars also contributes to the decrease of the reaction velocity. The phenomenon is consequently a non-specific retardation rather than a true inhibitory effect, which is non-competitive in type, and which should be called 'retardative inhibition' in order to distinguish it from the other types of inhibition. A similar mechanism plays a part in the protective effect of glucides against the heat inactivation of trypsin[4].

Table 1. INHIBITORY EFFECT OF DIFFERENT GLUCIDES ON TRYPSIN ACTIVITY

Glucide	Concentration of glucide (M)	Trypsin activity %*
D-Arabinose	1	70·8
D-Glucose	1	70·0
D-Galactose	1	54·4
D-Mannose	1	84·3
D-Fructose	1	64·2
Maltose	1	58·8
Maltose	0 5	80·9
Saccharose	1	54·8
Saccharose	0·5	77·1

* Trypsin activity as percentage of activity in the absence of glucides.

Tumour-promoting and Tumour-inhibiting Fractions from Tumours

RELATIVELY simple preparatory procedures reported from our laboratories[1] have been extended to obtain tumour-promoting fractions (MF_1 and MF_2) and a tumour-inhibiting fraction from lyophilized ascites sarcoma 37 (carried in *BT* mice) and *dbrB* adenocarcinoma (carried in *DBA*/1 mice).

The lyophilized tumour tissue was ground with 4 per cent sodium taurocholate, centrifuged, and the residue treated again with sodium taurocholate. Supernate and residue were combined, shaken, taken to *p*H 7·4 with sodium hydroxide, acidified to *p*H 6·6 with acetic acid, and centrifuged: from this treatment we obtained residue 1 and supernate 1. Residue 1 was washed with sodium taurocholate, extracted twice with acetone, centrifuged, and the final residue, dried *in vacuo*, was fraction MF_1. Supernate 1 was passed through a Seitz filter, the filtrate was brought to *p*H 4·3 with acetic acid, and the precipitate which formed (residue 2) was separated by centrifuging to give supernate 2. Residue 2 was extracted with acetone–water (1 : 1), centrifuged and re-extracted with acetone. The final residue, separated by centrifuging and dried *in vacuo*, was fraction MF_2.

Supernate 2, after Seitz filtration, was adjusted to *p*H 7 with sodium hydroxide and lyophilized. It was then extracted with benzene–ethanol (2 : 1), centrifuged and re-extracted with benzene–alcohol, and the insoluble portion was dried *in vacuo*. It was treated with absolute alcohol, and the soluble supernate separated by centrifuging and evaporated nearly to dryness on a water bath. Addition of ether produced a flocculent white precipitate which was the inhibiting fraction: this was separated by drying *in vacuo*.

Assays of MF_1 and MF_2 fractions from Sarcoma 37 and *dbrB* adenocarcinoma were made in *BT* and *DBA*/1 mice, respectively. The inhibitory fraction was investigated only against the *dbrB* tumour. 0·1 ml. of sarcoma 37 as a 1 : 5 dilution of ascites fluid from a donor was injected subcutaneously into the abdominal region of *BT* mice. The *dbrB* tumour was prepared as a 1 : 1,500 dilution of Type *B* suspension previously described[2] and 0·05 ml. was injected subcutaneously in the abdominal region of *DBA*/1 mice. Five days after tumour inoculation the appropriate fraction was injected intravenously into the tail vein. Fractions MF_1 and MF_2 were homogenized in distilled water (11 mg per ml.) and 0·05 ml. was administered. The inhibiting fraction was given in a 0·1-ml. dosage containing 33 mg per ml. Groups of ten to twelve mice were used for each experiment and control group (which only received the tumour material). Measurements were made of tumour size every 2 days, beginning on the fifth or sixth day after challenge. All control animals

developed tumours. At 10–11 days' post-challenge the sarcoma 37 tumour in mice which received MF_1 and MF_2 were 84–115 per cent and 20–30 per cent larger, respectively, than the tumours in the control mice. At similar periods the *dbrB* tumour was 51–53 per cent larger in mice which received MF_1 and 75–122 per cent larger in those which received MF_2. Greater differences were usually observed at earlier readings as the control tumours tended to catch up with the experimental ones as the post-challenge time increased. With the inhibiting material 50 per cent of the *DBA*/1 mice failed to develop palpable tumours and tumour growth was slow in the remaining mice. As the period of observation increased, the tumours which grew in the treated mice tended to overtake the control tumours so that at 27 days' post-challenge they were only 12 per cent smaller than those in the untreated mice, a figure of doubtful significance.

The techniques used for preparation and analysis of RNA and DNA generally followed the procedure of Kleinschmidt and Manthey[3]. Quantitative estimations were based on the procedure of Vischer and Chargaff[4]. RNA components were present in the MF_1 and MF_2 fractions and were concentrated in the latter. For MF_1 the mole per cent ratio $\frac{\text{adenine/uridylic acid}}{\text{guanine/cytidylic acid}}$ was 0·84. For MF_2 the ratio was 0·93. Hydrolysis studies of DNA components were less successful. The $\frac{A/T}{G/C}$ ratio for DNA of MF_1 was considerably less than one, and DNA from MF_2 gave poor chromatograms. Purines were present in small quantities and the pyrimidines gave diffuse light blue spots under ultra-violet which could not be satisfactorily resolved for quantitative determinations. Qualitatively similar results were obtained with a spontaneous mammary adenocarcinoma from *C3H* mice, but higher concentrations of purines were found in sarcoma 37. These pyrimidine abnormalities were not encountered in MF_2 fractions from mouse spleen or kidney or in sodium deoxyribonucleate subjected to the same hydrolytic procedure.

The protein moiety from MF_1 of *dbrB* adenocarcinoma contained aspartic acid, glutamic acid, serine, alanine, valine, phenylalanine, isoleucine, proline, threonine, histidine, lysine, and arginine. Phenylalanine and threonine were lacking in MF_2 which contained taurine. Nitrogen contents of MF_1 and MF_2 were 14·6 and 12·9 per cent respectively. The corresponding phosphorus values were 0·11 and 0·09 per cent. MF_1 and MF_2 from sarcoma 37 and *dbrB* adenocarcinoma gave an ultra-violet absorption maximum at 264 mμ and minimum at 242 mμ. Infra-red spectra of both fractions from all tumours (sarcoma 37, *dbrB*, and *C3H*) gave the expected protein absorption at 3μ, 6·1μ, and 6·5μ. Qualitative analysis revealed *d*-ribose and a deoxysugar.

The tumour-inhibiting fraction contained phosphorus and chlorine but was negative for nitrogen, sulphur, sugars, and protein. Infra-red spectra showed peaks at 3·1, 6·45, and 7·2μ; a slight shoulder at 7·5μ; and peaks at 9·82 and 10·8μ. In limited experiments, heating during final drying seemed to destroy the effectiveness of the tumour-inhibiting fraction.

PHYSIOLOGY

Chemical Transmission at the Insect Excitatory Neuromuscular Synapse

GLUTAMIC acid mimics the transmitter at the crustacean excitatory neuromuscular synapse[1] and has been tentatively identified with the chemical mediator at the insect peripheral excitatory synapse[2,3]. Similarities in the pharmacology of insect and crustacean excitatory neuromuscular synapses are, perhaps, to be expected since the pharmacological properties of their peripheral inhibitory synapses are remarkably similar[2,4]. In an effort to determine the site of action of glutamic acid on the insect neuromuscular system we have examined the effects of this substance on the electrical and mechanical properties of a locust neuromuscular preparation.

Most pharmacological and electrophysiological investigations of insect neuromuscular systems have, in the past, been made on *in situ* preparations of the larger orthopteran muscles. Because these large, complex preparations are not very suitable for pharmacological investigations we decided to use the locust metathoracic retractor unguis muscle, since this is a small muscle and can be isolated from the insect and kept alive for many hours if perfused with saline[2]. The muscle, which is about 1 cm long and 300μ in diameter and rarely contains more than 20 fibres, was dissected from the locust leg and fixed with a portion of its innervating nerve in a small 'Perspex' chamber and perfused continuously with saline or saline-containing drug. The muscle was stimulated indirectly through platinum electrodes placed on the innervating nerve. Measurements of the electrical properties and recordings of the electrical activity of the muscle fibres were made using conventional intracellular microelectrode techniques. Contractions of the muscle were recorded by attaching the apodeme of the retractor unguis muscle to a strain gauge with terylene thread.

A single phasic contraction of the retractor unguis muscle occurred when the preparation was perfused with glutamic acid (sodium salt) concentrations greater than 10^{-7} w/v (Fig. 1*b*). Maximal glutamate contractions were obtained with concentrations of about 10^{-5} w/v. In the presence of these relatively high concentrations of glutamic acid the neurally-evoked contractions elicited by maximal stimulation of the motor innervation were always reduced in magnitude and sometimes disappeared completely. At the same time, changes in the electrical properties of the muscle fibres were recorded. For example, the membrane potential and effective resistance were initially reduced when the preparation was perfused with concentrations of glutamic acid greater than 10^{-8} w/v (Figs. 2 and 3). Desensitization of the muscle glutamate receptors during prolonged exposure to high concentrations of glutamic acid led, however, to a slow return of the membrane potential and effective resistance to their resting control values (Fig. 3). Concomitant recovery of the neurally-evoked mechanical responses did not occur (Fig. 1*b*) yet the glutamate-insensitive muscle fibres contracted in response to direct electrical stimulation. The decline in magnitude of the neurally-evoked contractions is therefore indicative of transmission failure at the excitatory neuromuscular synapse and not of some effect of glutamic acid on either the electrically excitable membrane or contractile component of the muscle fibre. Transmission failure could be explained by assuming that glutamic acid is the excitatory transmitter. In the presence of high concentrations of this substance the glutamate receptors on the excitatory post-synaptic membranes would be desensitized and transmission blocked. Glutamic acid has, in fact, been identified in the perfusate obtained from the cockroach limb during stimulation of the nerves innervating the limb muscles[3].

The electrical properties of the muscle fibres were not affected by low concentrations of glutamic acid (that is,

concentrations less than 10^{-8} w/v). However, potentiation of the neurally-evoked mechanical responses (Fig. 1*a*) and an increase in the frequency of the miniature excitatory post-synaptic potentials[5,6] occurred during applications of 10^{-12} w/v to 10^{-9} w/v glutamic acid. Since there was apparently no concomitant change in the amplitude of the miniature discharge it is unlikely that potentiation of the neurally-evoked contractions was due to sensitization of the excitatory post-synaptic membrane. Possibly, glutamic acid facilitates the release of excitatory transmitter from the pre-synaptic terminals. With high concentrations of glutamic acid this process would be masked by the changes at the post-synaptic membrane. If glutamic acid is the excitatory transmitter then its pre-synaptic action could be the basis of neuromuscular facilitation at the insect peripheral excitatory synapse.

The cholinesterase found at the end plates on vertebrate striated muscles is thought to limit the action of the excitatory chemical mediator, acetylcholine, on the post-synaptic membrane. Enzymatic breakdown of the chemical mediator at the insect neuromuscular synapse has not yet been demonstrated. It is perhaps significant, however, that when the locust retractor unguis preparation was perfused with saline containing relatively low concentrations of glutamic decarboxylase (10^{-5} w/v of *E. coli* extract; activity 0·6 u./mg), an enzyme which converts glutamic acid to γ-aminobutyric acid (GABA), the mechanical responses elicited by nerve stimulation were reduced in magnitude (Fig. 1*c*). On the other hand, the contractions were potentiated when the muscle was perfused with relatively low concentrations of glutamic decarboxylase inhibitor, phenylhydrazine hydrochloride (Fig. 1*d*). Repetitive contractions of the muscle fibres to single shocks applied to the innervating nerve occur with concentrations of enzyme inhibitor greater than 10^{-5} w/v. Neither glutamic decarboxylase nor phenylhydrazine appears to have any effect on the electrical properties of the insect muscle fibre.

These observations suggest that glutamic acid could be the excitatory transmitter and that a glutamic acid–glutamic decarboxylase system could be the basis for

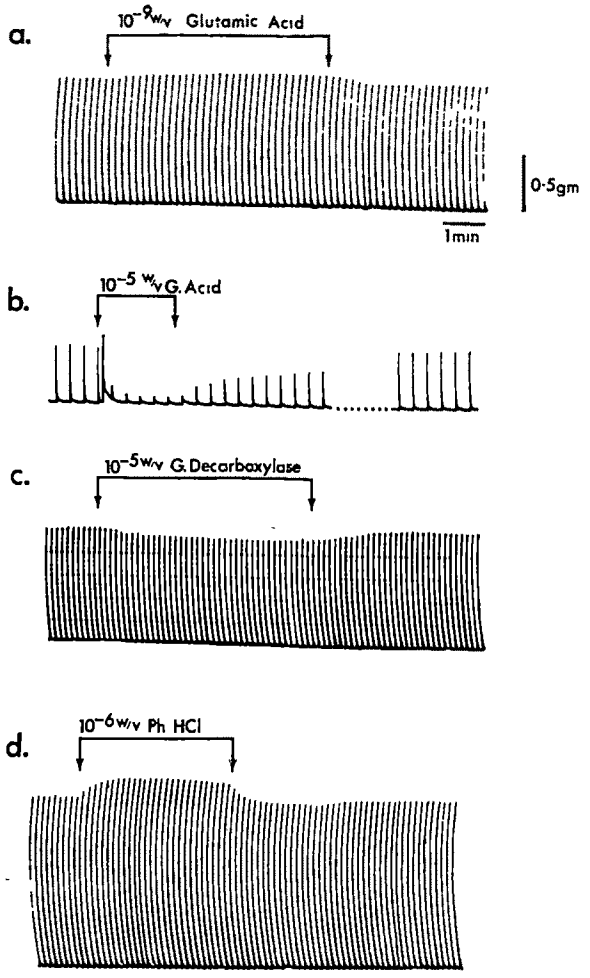

Fig 1. *a*, Potentiation of neurally-evoked contractions of retractor unguis muscle by a low concentration of glutamic acid (10^{-9} w/v). *b*, Maintained depression of neurally-evoked contractions in a relatively high concentration of glutamic acid (10^{-5} w/v). A glutamate-evoked phasic contraction of the muscle occurred immediately following application of the drug. *c*, Depression of neurally-evoked contractions by the enzyme, glutamic decarboxylase (10^{-5} w/v). *d*, Effect of the glutamic decarboxylase inhibitor, phenylhydrazine hydrochloride (10^{-6} w/v), on the neurally-evoked contractions. The mechanical responses are initially potentiated but after a short period the response height started to fall. The decline in magnitude of the contractions could be due to desensitization of the excitatory receptors following accumulation of transmitter at the post-synaptic membrane

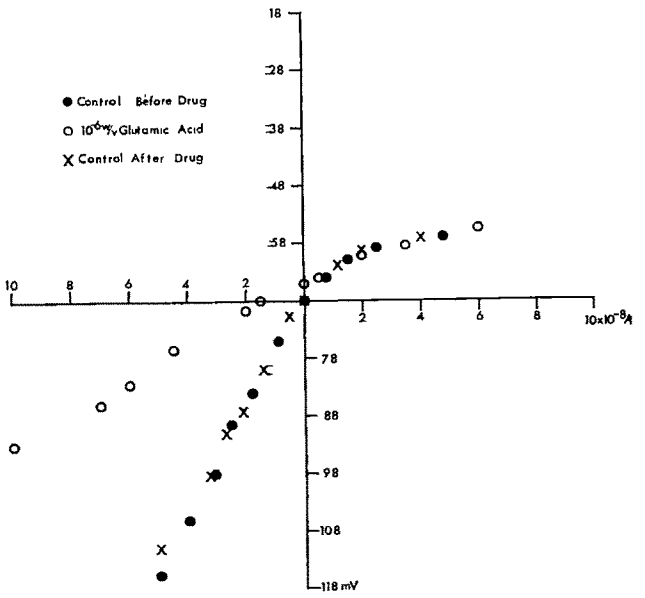

Fig. 2. Current-voltage relation of a single fibre (resting potential = 68 mV) of a locust retractor unguis muscle before, during and after treatment with a relatively high concentration of glutamic acid (10^{-6} w/v). The effective resistance of the muscle fibre fell by almost 70 per cent during application of the drug

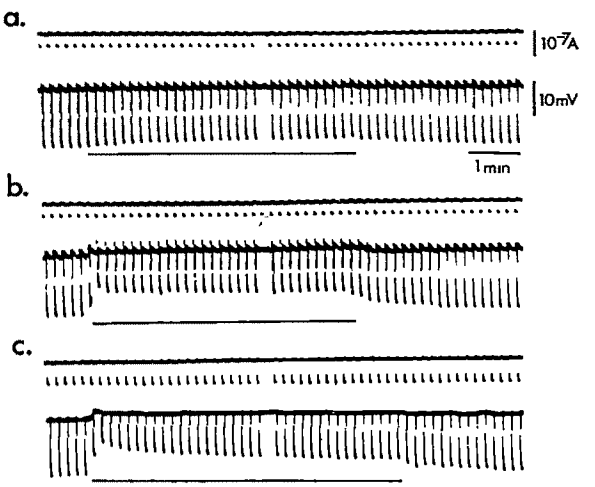

Fig. 3 Hyperpolarizing potentials (lower traces) to constant inward current pulses (upper traces) recorded from three different fibres of a single retractor unguis muscle (membrane potentials (*a*) 75 mV, (*b*) 72 mV, (*c*) 70 mV) Reduction in magnitude of hyperpolarizing potentials during application of (*a*) 5×10^{-8} w/v, (*b*) 5×10^{-7} w/v, and (*c*) 5×10^{-7} w/v glutamic acid indicates changes in effective resistance of muscle fibres. The muscle was perfused with drug during the periods indicated below the lower trace of each record. Note, especially in (*c*), initial fall in membrane resistance followed by slow recovery towards resting control condition

transmission at the insect excitatory neuromuscular synapse. One of the products of the enzymatic destruction of glutamic acid by glutamic decarboxylase, GABA, is known to mimic the transmitter at the insect inhibitory neuromuscular synapse[2,3]. If neuromuscular facilitation at the inhibitory synapse is due to the action of GABA on the terminals of the inhibitory axon then the appearance of GABA as an end product of excitatory neuromuscular transmission could have far-reaching implications.

Effect of Microwave Radiation on Birds

MUCH has been written over the past years on the effect of microwave radiation on body tissues and animals, but most of the experiments reported have been concerned with the production of heat and its associated behavioural and physiological effects[1-4]. There are very few references to 'athermal' effects such as muscular disturbances[5] and disorientation—phenomena which have not attracted the scientific attention that they merit. In fact, there appears to have evolved a body of opinion dismissing the existence of any effect other than a thermal one on the pretext stated in one report[4] that the photon energy in the frequency band of microwave radiation is insufficient by several orders of magnitude to produce ionization. Apparently no consideration has been given to the effect of induced electrical currents on the activity of the nervous system of an animal. Animal tissues absorb microwave radiation diffusely and since such tissues contain membrane interfaces which are semi-conducting, polarization can occur. If the microwave radiation is in pulsed form, the induced electrical currents will be modulated at the frequency of pulse repetition. It has been demonstrated experimentally that nerve conduction characteristics undergo a profound change when the nerve is subjected to a.c. excitation[6]. Therefore, it is to be expected that microwave radiation would have an effect on the nervous system of an animal depending on the depth of penetration.

Experiments have been conducted on chickens (Old English Games) fourteen weeks old at power levels in the range 10–30 mW/cm^2, at a frequency of 16,000 Mc/s and a pulse repetition rate of 8,000 pulses per sec. A horn antenna was arranged so that it could be mounted above, below or at the side of the cage. With the antenna mounted vertically above the cage it was observed, a few seconds after the onset of radiation, that sustained extensor activity of a wing and leg occurred—a reaction possibly due to the penetration of induced electrical activity to the spinal cord. Shielding first the head of the chicken, and then the body leaving the head exposed produced no significant change in the manifested extensor activity. Radiation from the antenna when mounted below the floor of the cage and pointing vertically upward produced no signs of muscular disturbance, although each chicken did register a startled reaction at the onset of radiation.

These experiments were repeated using pigeons and seagulls (ringbill) with similar but less dramatic results. The pigeons generally registered distress and unsteadiness of gait but not as pronounced extensor reactions. However, it was observed after the experiments that the wings of the exposed birds did not return to their normal fully retracted position for a period of an hour or more.

The seagulls registered considerable distress and unsteadiness of gait but shrugged off the muscular disturbance by repeatedly flapping their wings. There was no observable change in the retracted position of their wings.

Tests were made on the absorption characteristics of the feathers of each species, but the findings were negative.

It is suggested that the low field intensity and short exposure times (less than 60 sec) used in these experiments preclude the production of heat as the causal factor in the manifestation of extensor activity. Further experiments are planned to determine the phenomenological relationship between wave-length, pulse repetition rate and field intensity.

Action of Mecholyl on the Respiration of Cardiac Muscle *in vitro*

UNTIL now relatively little experimental evidence has been acquired about the detailed regulative function of acetylcholine (ACh) on the metabolism of cardiac muscle. Earlier investigations using the heart–lung preparation showed the oxygen-sparing effect of ACh (ref. 1). ACh seems to increase the energetic efficiency and to preserve the energy sources of the heart muscle tissue[2]. This problem, however, has not been completely solved even by analysis of the direct action of ACh on the cardiac muscle fibre. There are only a few reports on the sparing effect of ACh *in vitro*. An increase of adenosine triphosphate (ATP) and glycogen content in cardiac muscle treated with ACh has been reported[3]. Changes in the oxygen uptake of slices treated with ACh have also been shown by some workers[4]. Recently, the application of ACh or eserine *in vivo* has been shown to decrease the fatty acid utilization of minced myocardial tissue[5].

To obtain further information about this problem, we have studied the effect on the respiration of the isolated rat auricle and tissue slices from both ventricles of mecholyl(acetyl-beta-methylcholine chloride) (MCh) and eserine salicylate *in vitro*. MCh was used instead of ACh because of its small sensitivity to the inactivating action of cholinesterases. The drugs were added to the tissue *in vitro*; the final concentration shown in the Tables refers to their salts. Metabolic activity was measured as oxygen uptake by the direct Warburg technique.

In the first series the action of eserine alone and in combination with MCh has been studied. The rate of respiration of the tissue was stimulated by sodium succinate in the atmosphere of pure oxygen. The results obtained are shown in Table 1. Only slices of left ventricle tissue showed any marked depression of metabolic activity during the second hour of incubation. The final effective concentration of the combined eserine–MCh action cannot, however, be considered a physiological one. It seems of interest that the oxygen uptake of the other myocardial parts remained largely unaffected. Eserine alone (even at concentrations as high as 200 μg/ml.) produced no effects.

In the second series the control respiration rate of the cardiac tissue specimens was diminished by omitting the

Table 1. OXYGEN UPTAKE OF CARDIAC TISSUE *in vitro* AFTER ESERINE AND ESERINE+MECHOLYL (MCh) AT THE HIGHER RATE OF RESPIRATION

Tissue	μl Oxygen/100 mg wet wt /90 min Eserine	Eserine+MCh
Isolated auricles	421·6±21·1 (9)	457 4±19 1 (6)
Slices: left ventricle	354·8± 9·5 (8)	283 0± 7·3 (5)
right ventricle	338 9±19·8 (8)	322 6±26·8 (5)

Medium buffered Krebs-Ringer solution with 0 2 per cent glucose and 20 mM sodium succinate. Eserine salicylate 200 μg ml., MCh=200 μg mecholyl chloride/ml. Gas phase: 100 per cent oxygen, $t=37°$ C. Values are the means ±*S.E.*, figures in parentheses are numbers of experimental animals. Inhibition after mecholyl in left ventricular slices is significant.

Table 2. OXYGEN UPTAKE OF CARDIAC TISSUE *in vitro* AFTER ESERINE +MECHOLYL (MCh) AT THE LOWER RATE OF RESPIRATION

Tissue	μl. Oxygen/100 mg wet wt./90 min Control	Eserine+MCh
Isolated auricles	116 3±4·9 (8)	117·4±4 7 (8)
Slices: left ventricle	70·7±2·8 (7)	72·2±6·2 (8)
right ventricle	72·5±4·3 (7)	73·7±6·4 (9)

Experimental conditions the same as those in Table 1 with exception of the gas phase ($Po_2=0$ 21 atm.) and after omission of succinate. No inhibition after eserine+mecholyl was found.

sodium succinate and using air as the gaseous phase. Under these circumstances, even the aforementioned high combined dose of both cholinotropic drugs did not affect the oxidative metabolism of the three different specimens of myocardial tissue (Table 2).

These findings in sliced ventricular tissue and isolated auricles at the two different levels of respiration used do not support the suggested action of MCh on cardiac energetic metabolism at the cellular level. It seems clear that the sensitivity of the cardiac tissue *in vitro* to MCh and eserine as tested by the Warburg method is surprisingly small. In this connexion, a certain analogy with the behaviour of brain slices treated with ACh *in vitro* may be mentioned. Although there is no doubt about the physiological importance of ACh in the central nervous system, experiments with slices or homogenates of the brain cortex using cholinotropic agents failed to show any effect on the oxidative metabolism of the tissue[6,7].

Variations in the Plasmalogen Content of Mammalian Heart Muscle

MAMMALIAN heart muscle contains about one-quarter of its phospholipid, on a molar basis, in the plasmalogen form. Unlike brain, where the plasmalogen is almost entirely in the ethanolamine form (glycerol 2-acyl-1-alkenyl-3-phosphorylethanolamine)[1], heart muscle contains both the ethanolamine and choline plasmalogen.

It is also known that the ratio of ethanolamine to choline plasmalogen in the heart muscle of some young mammals is different from that of the adult. In the cardiac muscle of new-born dogs[2], for example, the choline : ethanolamine plasmalogen ratio is low whereas in the adult heart the choline plasmalogen level is very much higher than that of the ethanolamine analogue.

This variation in the ratio of choline to ethanolamine plasmalogen does not, however, appear to be a function only of age. There is a considerable variation within the adults of different species as can be seen in Table 1. Adult rats, mice and sheep, and to a lesser extent ferrets, have a high ethanolamine : choline ratio in their plasmalogens. The hearts of cats, guinea-pigs and ox, however, have a much higher choline : ethanolamine ratio, approaching the 'adult' situation described by Hack and Helmy[2]. Apart from rat, mouse and sheep where the

Table 1 PLASMALOGEN CONTENT OF THE CARDIAC MUSCLE IN SEVERAL MAMMALS

Species	Plasmalogen as mole % total phospholipid	Plasmalogen μmoles/g heart Choline	Ethanolamine	Molar ratio choline : ethanolamine
Rat	13	0 4	3 0	1 : 7 5
Mouse	13	0 8	3·5	1 . 4·4
Sheep[6]	18	1·6	3·7	1 · 2 3
Ferret	25	2·4	4·7	1 2·0
Cat	27	2·9	3 2	1 1 1
Ox	26	2 5	2 3	1 0 9
Guinea-pig	34	3 6	3 3	1 : 0 5

In the experiments, the ethanolamine and choline plasmalogens were determined by the method of Dawson, Hemington and Davenport (ref. 3) using the modification of Ansell and Spanner (ref 4). Total plasmalogen was also determined by the method of Gottfried and Rapport (ref 5).

percentage of phospholipid in the plasmalogen form is low (13–18 per cent), the values lie between 25 per cent and 34 per cent. It would seem that it is the lack of choline plasmalogen rather than an increase in ethanolamine plasmalogen that accounts for the low choline : ethanolamine ratio (Table 1). Until the role of the plasmalogen in heart muscle is known, however, it is difficult to know if the variation in the choline : ethanolamine plasmalogen ratio is of any physiological importance.

Laser Lesions : Changes in Retinal Excitability

THE electroretinogram and optic tract potentials evoked by photic stimulation exhibit complex changes following the production of a chorioretinal lesion by a pulsed laser beam. Retinal function is not only permanently modified by the lesion, but its production is accompanied by temporary and possibly widespread changes in retino-optic nerve excitability.

Experiments were carried out on cats, weighing between 1·5 and 2·5 kg, anaesthetized by the intravenous injection of pentobarbitone-sodium (30 mg/kg). The right eye was enucleated and the pupil of the left eye fully dilated by the intramuscular injection of atropine sulphate (0·6 mg) and the local application of a mydriatic (phenylephrine hydrochloride). Electroretinograms were recorded with a chlorided silver electrode resting on the rim of the cornea in the upper and outer quadrant, and optic tract potentials were recorded from co-axial electrodes inserted stereotaxically. The photic stimulus was generated by a Mazda '*FA*10' flash tube placed in front of the eye, control responses and responses immediately following the lesion being recorded without interruption. Each lesion was produced in the nasal part of the retina by a ruby rod laser of nominal output 0·5 J and pulse duration 0·5 msec; the lesions varied in diameter from 0·4 mm to 2·2 mm.

In the first series of experiments, using nine cats, the electroretinogram and optic tract potential from the nasal part of the retina were recorded every 2 sec. The *A* and *B* waves of the electroretinogram were depressed immediately following the lesion (Fig. 1): although the *A* wave regained almost complotely its control amplitude, the *B* wave, following an initial recovery, progressively declined over the following 50 min. The optic tract potential was also reduced in amplitude immediately following the lesion and the reduction varied from 18 per cent of the average control amplitude to a complete disappearance (Fig. 1). In most experiments this potential made a partial recovery and in one experiment the control amplitude was regained.

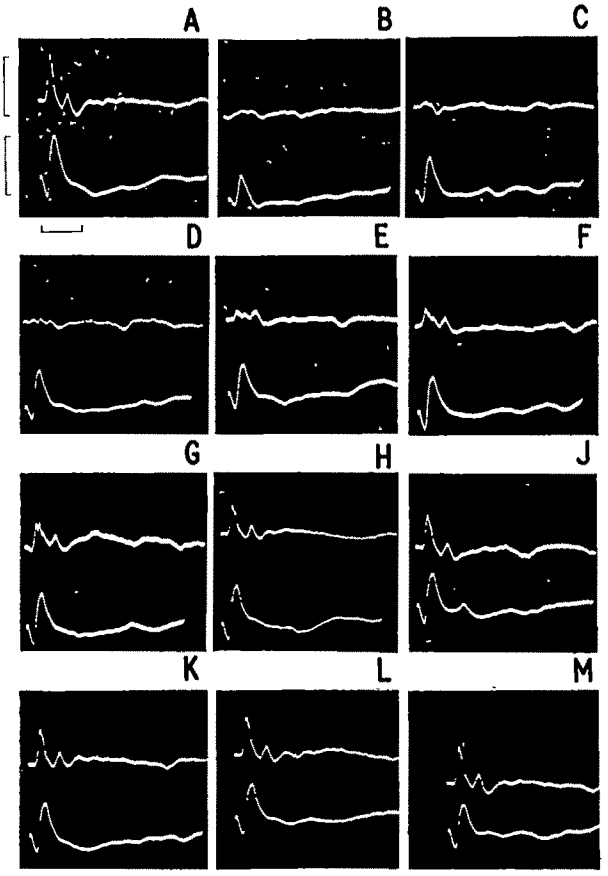

Fig. 1. Effect of a nasal chorioretinal lesion on both the electroretinogram (lower trace) and the nasal optic tract potential (upper trace): *A*, Control records. *B*, *C*, *D*, Responses approximately 2, 6 and 12 sec after the lesion. *E*–*M*, Responses at the 1, 3, 5, 10, 15, 20, 30, 40 min interval after the lesion. The immediate effect is a complete disappearance of the optic tract potential and a fall in the amplitude of the *A* and *B* waves of the electroretinogram. The optic tract potential exhibits a partial recovery but the electroretinogram shows a depression of the *B* wave after an almost complete recovery. The *A* wave of the electroretinogram maintains the recovery observed within the first min. Calibrations: 300 μV and 100 msec

In the second series of experiments, electrodes were placed in both optic tracts and a lesion produced in the nasal part of the retina. In seven of the nine experiments the temporal optic tract potential showed no change during the 40-sec period after the production of the lesion, but in the remaining two experiments the potential showed a decrease which recovered within this period. As in the previous experiments the potential recorded from the nasal optic tract immediately following the lesion was decreased in amplitude.

In these experiments the relation between the electrode and the fibres originating from the part of the retina in which the lesion was made was not known, but it is reasonable to assume that the changes in optic tract potentials are dependent on the spatial relationship between their retinal connexions and the lesion. We consider that changes in potentials recorded from the optic tract of the damaged part of the retina, and the transient fall in amplitude sometimes observed in potentials recorded from the optic tract of the undamaged part of the retina, suggest not only localized permanent damage but also a temporary disorganization of retino-optic mechanisms. The depression in the electroretinogram immediately following the lesion is additional evidence for a change in retinal excitability which may be widespread.

PHARMACOLOGY

A New Type of Cytotoxic Immunosuppressive Agent: 3-Acetyl-5-(4-fluorobenzylidene)4-hydroxy-2-oxo-2:5-dihydrothiophen

DURING the past 3 years we have been investigating the biological properties of a series of thiophens of the following general formula (I):

I

in which *R* is an alkyl or alkoxy group and the substituent *X* is an electron-withdrawing group such as halogen or nitro. These investigations resulted from the observation that the compound I.C.I. 45,514 (I, *R* = ethoxy, *X* = H) prevented the development of secondary inflamed lesions in rats injected into the foot-pad with a fine suspension of dead tubercle bacilli in liquid paraffin. The use of this syndrome for evaluating chemotherapeutic agents has already been described[1,2].

This communication describes the properties of one of the more active compounds in the series, I.C.I. 47,776 (I, *R* = methyl, *X* = 4-fluoro), which may be prepared by condensation of 4-fluorobenzaldehyde with 3-acetyl-4-hydroxy-2-oxo-2 : 5-dihydrothiophen under either acidic or basic conditions[3]. It melts at 183° C and is soluble in most organic solvents and as its salts in water. It may exist in tautomeric forms other than that indicated. Recently we have found that aqueous suspensions of I.C.I. 47,776 slowly isomerize at room temperature, and special precautions are necessary to ensure that full-strength material is used in small animal experiments. These include grinding under dry conditions and storing aqueous suspensions at 0° C. The isomer is relatively non-toxic and inactive. Compounds in which *R* is alkoxy rather than alkyl do not isomerize.

In chemotherapeutic tests, I.C.I. 47,776 (5–10 mg/kg/day orally) prevented the development, or reduced the severity of secondary inflamed lesions in rats injected with adjuvant into the foot-pad. Similar doses also prevented the development of allergic thyroiditis and allergic encephalomyelitis in the rat, but in a variety of standard anti-inflammatory tests the compound was inactive.

I.C.I. 47,776 proved to be a potent inhibitor of protein and nucleic acid synthesis in suspensions of rat lymph node cells in Eagle's medium (85–95 per cent inhibition at 15 μM). Similar effects were observed with rat liver cells and slices, mouse *L* cells, Landschutz ascites cells and guinea-pig lymph node cells. That inhibition is probably due to interference with generation of high-energy phosphate esters necessary for macromolecular synthesis was demonstrated by inhibition of nicotinamide adenine dinucleotide linked oxidations in isolated mitochondria (95 per cent inhibition at 5–10 μM). This is in contrast with the actions of most cytotoxic drugs which interfere directly with nucleic acid metabolism. Concentrations of I.C.I. 47,776 similar to those which inhibited oxidations in isolated mitochondria also increased the activity of the Mg^{++} dependent adenosine triphosphatase in mitochondria but strongly inhibited the adenosine triphosphatase activated by 2,4-dinitrophenol.

The foregoing results led us to suppose that I.C.I. 47,776 might act *in vivo* as an immunosuppressive agent. This view was confirmed by suppression of the primary antibody response in rats to bovine serum albumin or sheep red cells at a dose of 5 mg/kg/day orally. Moreover, in rats injected with adjuvant into the foot-pad the

development of large pyroninophilic cells and plasma cells in the draining lymph nodes was prevented. Such cells are considered to be involved in antibody synthesis.

Preliminary toxicity investigations with I.C.I. 47,776 in rats and mice have demonstrated haematological and histological changes characteristic of the effects of cytotoxic agents and ionizing radiation. The degree of the effect is closely related to the dose given and parallels the immunosuppressive action already discussed. Because I.C.I. 47,776 has a different mode of action from the cytotoxic agents which are at present available it may prove of interest to study its activity in the treatment of certain malignancies and diseases which involve the participation of an immune response.

An Anti-viral Drug (M and B 7714) and Bilirubin Conjugation

M AND B 7714 (4-bromo-3-methylisothiazole-5-carboxaldehyde thiosemicarbazone) is a thiosemicarbazone recently introduced for the treatment and prevention of smallpox[1]. The mode of action of M and B 7714 is similar to methisazone but it is slightly less active against rabbit pox[2]. In clinical trials a number of patients have developed an unconjugated hyperbilirubinaemia, and chronic administration of the drug to animals produces an unconjugated hyperbilirubinaemia[3]. I have examined the effect of M and B 7714 on conjugation and biliary excretion to determine the possible site of action of the drug causing jaundice.

The rate of bilirubin glucuronide formation was determined in rat liver slices and rabbit liver homogenates by the method of Lathe and Walker[4]. *o*-Aminophenol conjugation was determined in rat liver slices by the method of Levvy and Storey[5]; in rabbit liver homogenates by the method of Stevenson and Dutton[6]. M and B 7714 was dissolved in ethanol and the ethanol evaporated; the final concentrations were 0·01, 0·1, 1·0 and 10 mM. The effect of M and B 7714 on the maximum hepatic clearance of bromsulphthalein and indocyanine green was determined in male Wistar rats. The maximum hepatic clearance of bilirubin[7] was determined together with the amount in the liver[8] after intraperitoneal injection of the drug.

The addition of M and B 7714 did not lower the rates of conjugation of bilirubin and *o*-aminophenol by rat liver slices. The transferase (UDP glucuronate glucuronyl transferase (acceptor unspecific) *EC*. 2.4.1.17) stage of conjugation was examined in rabbit liver homogenates incubated with ample added uridine diphosphate glucuronic acid. M and B 7714 did not alter the rates of conjugation of these substances by liver (Table 1).

10 mg/100 g, 20 mg/100 g and 30 mg/100 g M and B 7714 suspended in propylene glycol were injected intraperitoneally 1 h before the infusion of bilirubin, indocyanine green and bromsulphthalein. 30 mg/100 g M and B 7714 reduced the maximum hepatic clearance of all three substances (Table 2). When bilirubin was infused, the uptake of bilirubin was not reduced but the percentage of conjugated bilirubin in the liver was decreased.

Table 1. EFFECT OF M AND B 7714 ON CONJUGATION

	Rate of conjugation (mμmoles/mg wet wt/h)			
	Rat liver slices		Rabbit liver homogenate	
Concentration (mM)	Bilirubin	*o*-Aminophenol	Bilirubin	*o*-Aminophenol

No. of experiments	(3)	(3)	(4)	(2)

Table 2. EFFECT OF M AND B 7714 ON MAXIMUM HEPATIC CLEARANCE

	Maximum hepatic clearance (μg/100g body-wt./min)			
Dose	Bilirubin	Percentage conjugated in liver	Brom-sulphthalein	Indocyanine green
Control	74(14)	75	73(8)	4·7(16)
10 mg/100 g	73(2)	80	—	3·5(1)
20 mg/100 g	61(4)	67	—	6·1(1)
30 mg/100 g	46(4)	52	25(3)	2·1(5)

No. of experiments in parentheses.

The effect of M and B 7714 on conjugation and biliary excretion was investigated to try and determine the site of action of the drug causing an unconjugated hyperbilirubinaemia. An unconjugated hyperbilirubinaemia can be due to defective uptake of bilirubin or defective conjugation. It is unlikely that defective uptake occurs because bilirubin is present in the liver in slice and infusion experiments in amounts comparable to control experiments.

The effect of M and B 7714 on the *in vitro* conjugation experiments is unusual; it may be that there is no effect because of the extreme insolubility of the compound. In the *in vivo* experiments the excretion of bilirubin and dyes and the amount of conjugated pigment in the liver are reduced; it is possible that the substance is converted *in vivo* to a hepatotoxic material which then inhibits glucuronyl transferase and dye excretion. No such transformation occurs *in vitro*.

I thank Valerie Price for her technical assistance, Prof. N. H. Martin for advice and encouragement, the British Empire Cancer Campaign, May and Baker Ltd., and the Board of Governors of St. George's Hospital for financial assistance.

Toxicity of Dimethyl Sulphoxide to the Goldfish, *Carassius auratus*

INVESTIGATIONS of the comparative toxicities of organic pesticides to fish have to some extent been hampered by the insolubility of these compounds in water. The most widely used solvent in such tests is acetone, but this compound has important disadvantages. Although it is relatively non-toxic to fish (in this laboratory goldfish have tolerated 18 p.p.t. for at least one week) acetone in solution has a high oxygen demand which may lead to oxygen depletion in the test media[1,2], and if the compound under evaluation, or the solvent vehicle, is volatile it is clearly undesirable to rely on artificial oxygenation.

The low mammalian toxicity of dimethyl sulphoxide (DMSO), together with its favourable volatility, miscible nature and solvent properties[3–5], suggested that this compound might offer certain advantages as an alternative solvent to acetone. Accordingly some preliminary toxicity tests with the goldfish were undertaken which are reported here.

The tests were conducted in Huntingdon tap water of hardness 32 deg., which has been shown to be non-toxic to

fish, at a temperature of 15° C. Fish were exposed in all glass aquaria of 15 l. capacity, each of which contained a maximum of five goldfish 2·0–2·5 in. long. Under these conditions, the 48 h median tolerance limits, or LC_{50} values, were found to be 24 p.p.t. for acetone and 43 p.p.t. for DMSO. At 32 p.p.t. DMSO five goldfish survived for ten days without exhibiting signs of respiratory stress or symptoms of toxic reaction. In a similar concentration of acetone the median period of survival was about 90 min.

Jacob *et al.*[6] have shown that, in a solution containing 15 per cent DMSO, certain compounds are transported across the dog urinary bladder mucosa at a more rapid rate than when they are dissolved in an equivalent strength acetone solution. At levels of 6 and 18 ppt DMSO in water containing 0·05 p.p.m. DDT (70–74 per cent *p.p'.* isomer. A gift from Cocker Chemical Co. Ltd., Oswaldtwistle), the median period of survival of goldfish has not been found to differ significantly from that in tests where the DMSO was replaced by an equivalent amount of acetone. In all tests the value lay between 15 and 24 h. This would tend to indicate that at these comparatively low concentrations DMSO is unlikely to affect unduly the rate of absorption of organic pesticides.

These results suggest that DMSO might be a more suitable solvent for organic pesticides being tested on fish than the more commonly used acetone. Possession of a lower order of toxicity means that quantities adequate to ensure more efficient dispersal of the pesticide in the test water can be used.

The main disadvantage of DMSO resides in its dipolar aprotic nature so that the possibility exists that certain compounds dissolved in it may undergo chemical change. It has already been noted, for example, that solutions of two organophosphorous compounds in DMSO undergo colour changes after 24 h[4].

HAEMATOLOGY

Haemoglobin Polymorphism in the Orang Utan and an Animal with Four Major Haemoglobins

IN examining haemolysates from ten orang utans from the Yerkes Regional Primate Center collection we found four different haemoglobin phenotypes including one in which three major haemoglobin zones were present. The samples, kindly supplied by Prof. G. Bourne and Dr. J. Moor-Jankowski, were first analysed on starch gels using a *tris*-ethylenediamine tetraacetic acid (EDTA) buffer system[1] and were later investigated by hybridization[2,3] of the component haemoglobins with various other haemoglobins.

Four animals had a single major component migrating slightly anodally to human Hb-A at *p*H 8·6; we refer to this as Hb-A^{OR} (Fig. 4*b*). A minor component similar to human Hb-A_2 in concentration but more anodal in mobility was also present in this phenotype. Two animals had a single major haemoglobin more cathodal than Hb-A^{OR} (Fig. 1*d*) and similar in mobility to the minor component already mentioned. We refer to this major component as Hb-B^{OR}. These animals also had a minor component but it was slower than Hb-B^{OR}. Three other animals had both Hb-A^{OR} and Hb-B^{OR} in similar concentrations (Fig. 1*c*) and a rather weak minor component of the slower type.

The last animal (No. 8) had three major haemoglobin zones and a weak minor component of the slower type (Fig. 1*a*). The middle zone (M) was the same as Hb-A^{OR} in mobility and the slow zone the same as Hb-B^{OR}. The relative strengths of the three zones eluted from a maize starch block were fast = 26·0 per cent, middle = 47·5 per cent and slow = 26·5 per cent, which suggests that the middle zone might contain two haemoglobins.

Human cases with more than two major haemoglobins have occasionally been reported[1]. They are explicable on the basis that both normal and abnormal α-chains and also normal and abnormal β-chains are synthesized. Combination of these chains *in vivo* yields four kinds of haemoglobin, Hb-A ($\alpha_2^A\beta_2^A$), and α-chain variant ($\alpha_2^X\beta_2^A$), a β-chain variant ($\alpha_2^A\beta_2^Y$) and the doubly abnormal type ($\alpha_2^X\beta_2^Y$). If the mobility of the last-named is the same as Hb-A only three zones are separated in electrophoresis.

If the phenotype of orang No. 8 was produced in this way the middle zone should contain both Hb-A^{OR} together with a haemoglobin with variant α- and β-chains. Treatment of this zone by the hybridization procedure should yield the fast and slow variants and this was found to be so (Fig. 2*a*, *b*). Similarly the isolated fast and slow zones when mixed and hybridized should yield the middle zone, which in fact they do (Fig. 2*c*, *d*).

The slow zone of orang No. 8 is indistinguishable electrophoretically from the component, Hb-B^{OR}, of five other animals. It is a reasonable assumption that the slow haemoglobin in all these animals is the same, although this could only be established by structural investigations.

It remains to determine whether Hb-B^{OR} differs from Hb-A^{OR} in the α- or β-chain. Hb-A^{OR}, unlike human Hb-A, forms no separable hybrids with Hb-canine[4], but two hybrids, respectively slower and faster than the

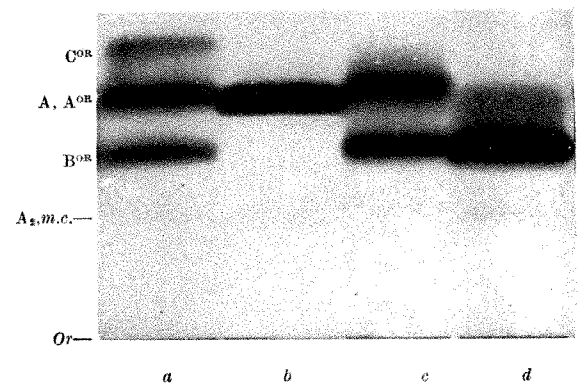

Fig. 1. *Or*, Origin; +, indicates anode. Some haemoglobin phenotypes of the orang. *o*-Tolidine/peroxide stain. (*a*), No. 8: three major Hb zones and slow minor component (*m.c.*); (*b*), human Hb-A and Hb-A_2; (*c*), Hb-A^{OR}, Hb-B^{OR} and slow minor component; (*d*), Hb-B^{OR} and slow minor component

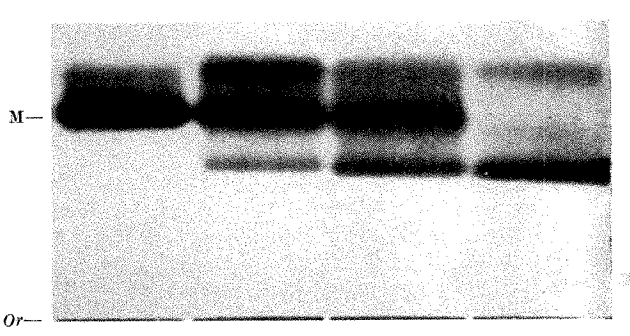

Fig. 2. Recombination of major zones from orang No. 8. *o*-Tolidine/peroxide stain. (*a*), Middle component (M); (*b*), middle component after hybridization treatment; (*c*), fast and slow components after hybridization treatment; (*d*), fast and slow components

parent species, are seen when it is recombined with human Hb-A (Fig. 3*b*). The more anodal of these hybrids was shown to have the same mobility as the single hybrid zone formed when Hb-A^{OR} is recombined with human Hb-H (β_4) and is therefore $\alpha_2^{A or}\beta_2^A$ (Fig. 3*a*). No separable hybrids were obtained when Hb-B^{OR} from two different animals and also the slow zone from No. 8 were recombined with Hb-A, suggesting that the α-chains of Hb-B^{OR} is less negatively charged than that of Hb-A^{OR} so that the hybrid $\alpha_2^{B or}\beta_2^A$ has the same mobility as Hb-A. Hb-B^{OR} also yielded no separable hybrids with human Hb-C, a slow β-chain variant, but gave two hybrid zones respectively faster and slower than the parent haemoglobins with Hb-canine. These results are consistent with Hb-B^{OR} having a variant α-chain. The fast zone from No. 8, which we will call Hb-C^{OR}, forms no separable hybrids with Hb-A or Hb-canine but yields two hybrid zones ($\alpha_2^A\beta_2^{Cor}$ and $\alpha_2^{A or}\beta_2^C$) lying between the parent haemoglobins, with Hb-C. These findings are consistent with Hb-C^{OR} having a variant β-chain.

Orang No. 8 and also those animals carrying Hb-B^{OR} have a minor component slower than that in animals with Hb-A^{OR} alone. This is explicable if the minor component of the orang like human Hb-A_2 is composed of an α-chain combined with another chain comparable with the δ-chain of man, though not necessarily the same in composition. Animals with Hb-B^{OR} would then be expected to form *in vivo* a minor component containing the variant α-chain, as happens with certain human α-chain variants such as Hb-G_α^5. In No. 8 and in heterozygotes also synthesizing normal α-chains the faster type of minor component would also be present but masked by Hb-B^{OR}.

The minor component was isolated from an animal with only Hb-A^{OR} as a major component by elution from a carboxymethyl cellulose column followed by electrophoresis on a maize starch block[5]. Equal volumes of this purified material (2 per cent) and human Hb-H (8 per cent) were then mixed and dialysed at *p*H 4·7 for 24 h.

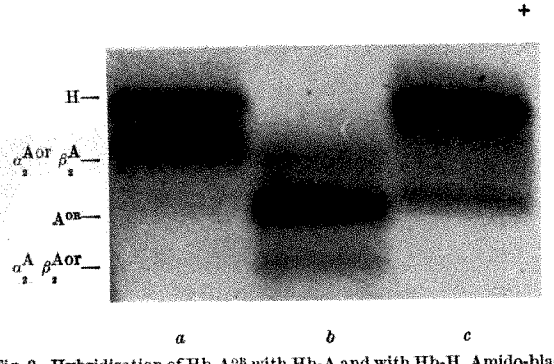

Fig. 3. Hybridization of Hb-A^{OR} with Hb-A and with Hb-H. Amido-black stain. (*a*), Hb-A^{OR} and Hb-H after hybridization; (*b*), Hb-A^{OR} and Hb-A after hybridization; (*c*), Hb-A^{OR} and Hb-H

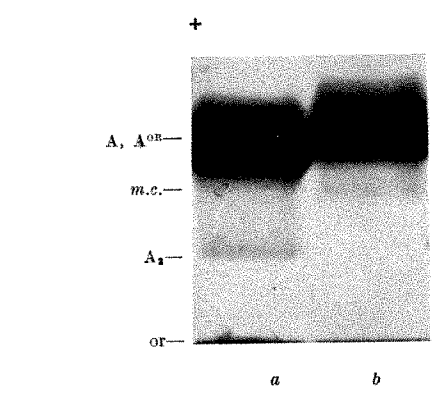

Fig. 4. (*a*), Hb-A and Hb-A_2; (*b*), Hb-A^{OR} and fast minor component (*m.c.*). *o*-Tolidine/peroxide stain

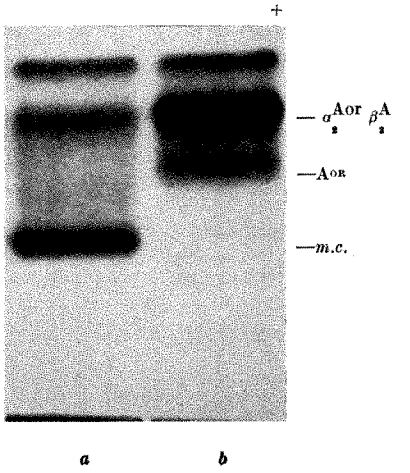

Fig. 5. (*a*), Minor component (fast type) after hybridization with Hb-H; (*b*), Hb-A^{OR} after hybridization with Hb-H. *o*-Tolidine/peroxide stain

After redialysis to *p*H 6·9 this material was compared on starch-gel with $Hb\text{-}A_{OR}$ mixed with Hb-H and treated in the same way (Fig. 5). The minor component with Hb-H yielded a hybrid zone of the same mobility as that formed by Hb-A^{OR} with Hb-H, suggesting that its α-chains are the same as those of Hb-A^{OR}.

It has been reported[6,7] that a minor component occurs in the chimpanzee and gorilla. We have found that a minor component very similar to human Hb-A_2 in mobility and concentration was present in every one of forty-two chimpanzees from the Yerkes collection and in one gorilla from this source. On the other hand, we have not found a minor component in specimens from several species of *Papio, Macaca mulatta M. cyclopis, M. speciosa, M. sinica, M.* (*Cynopithecus*) *nigra*[8], *Erythrocebus patas* and *Cercopithecus aethiops*. In *M. irus*, however, a minor component occurred in some 20 per cent of more than 200 animals. In contrast to human Hb-A_2 and, it appears, to the minor component of the orang, it contained a variant chain combined with a normal β-chain[9].

The high incidence of haemoglobin variants in this small sample of orangs is remarkable. The haemoglobin phenotypes of two other orangs (one from Borneo and one from Sumatra) have been reported[7] and each was considered to have two major components; however, comparison of the illustrations with our own material suggests that one had Hb-A^{OR} and a minor component and the other Hb-B^{OR} alone.

Unfortunately, we have very little information about the histories of the animals on which we have worked, but they were obtained at various times from dealers[10] and it seems unlikely that they are closely related animals from a restricted locality. Though it would be rash to regard them as a representative sample of the species, our results suggest that the variant Hb-B^{OR} may be very common in the orang. The incidence of cases like No. 8 will depend on the frequencies of the α- and β-chain variants involved, provided that such phenotypes are not subject to strong selection, and we may infer that another variant, Hb-C^{OR}, is also quite frequent unless we prefer to regard its occurrence in our small sample as a rare event.

Very little is known of the natural history of the orang[11], but its distribution is restricted to Borneo and Sumatra and it is probably the most numerically reduced of the great apes. Its decline has doubtless been accelerated by human interference in recent times. It is said to occur singly or in small groups but since these are believed to be inconstant in composition the breeding units are probably larger. Nevertheless, in view of the diminished numbers of the species as a whole, the mating populations may well be small enough for loss of variability by genetic drift to be appreciable and it is therefore interesting to find evidence that haemoglobin polymorphism persists. We

have also reported[9] polymorphism of haemoglobins and several other blood proteins in another asiatic primate of restricted distribution, namely *Macaca* (*Cynopithecus*) *nigra*, which is confined to the northern peninsula of Celebes.

The Quantitative Relationship of the Rh-like (LW) and D Antigens of Human Erythrocytes

PREVIOUS investigations have shown that the injection of human D-positive and negative, rhesus and other monkey red cells into guinea-pigs produces an Rh-like (LW) antibody which reacts more strongly with D-positive than D-negative red cells. The Rh-like (LW) antigen is absent from Rh_{null} (– – –/– – –) red cells and also from the blood of several unusual persons with apparently normal Rh antigens. Some of the latter individuals have produced LW antibodies which resembled those induced in guinea pigs by immunization with human and monkey red cells.

Several investigators[1,2] have reported that D positive red cells from a variety of genotypes, including the –D–/–D– cell with its exceptionally strong D antigen, give essentially the same titration score with human and guinea-pig anti-LW sera. Regis and Yunis[3], however, have recently reported that the LW reactivity of human erythrocytes with guinea-pig and anti-human red cell sera appears to decrease in the following order: cDE/cDE > cDe/cde > CDe/CDe > cde/cde. Gibbs and Rosenfield[4] also observed with hand titrations of a guinea-pig anti-rhesus reagent that the order of reactivity of the LW antigens of eight siblings of a family (Pr) appears to be the same as that of their D antigens: CDe/cde > CDe/CDe > cD^uE/cde > cD^uE/CDe. In view of the importance of these observations to the elucidation of the relationship of LW to the Rh system, it was of interest to confirm these findings with quantitative procedures.

The results of our preliminary investigations to determine whether there is a relationship between the LW and D activities of human erythrocytes are shown in Table 1. The bloods of the mother and a sibling of the Caucasian Rh_{null} propositus (Mrs. L. M.) were included in this study. Levine *et al.*[1] have reported that the Rh antigens of these individuals are abnormally weak but their LW antigens give normal indirect Coombs titration scores with human anti-LW serum. The 50 per cent endpoint titres listed in the table were obtained by the log-probit assay method of Wilkie and Becker[5] using precisely standardized suspensions of test cells. Antiserum-cell mixtures were equilibrated by the aggregation method (without centrifugation) with an incubation period of 3 h at room temperature for the guinea-pig sera and at 37° C for human sera. With all cells tested, the slopes of the anti-LW assay curves were parallel. The titres of the anti-LW sera correlated with the anti-D titres for all Rh genotypes tested. The human anti-LW serum gave the most distinct differentiation (16·7-fold difference between cDE/cDE and CDe/Cde cells); the guinea-pig anti-baboon serum proved the least effective, giving only a three-fold difference between the strongest and weakest D cells.

Table 1. 50 PER CENT ENDPOINT TITRES* OF ANTI-LW SERA WITH HUMAN RED CELLS OF VARIOUS GENOTPYES

	Guinea-pig sera†		Human sera	
	Anti-rhesus RBC (1:)	Anti-baboon RBC (1:)	Anti-LW (1:)	Anti-D (1:)
cDE/cDE	10·4	370	67	2,000
cDE/cde	5·9	250	N.T.	975
CDe/cDE	5·9	255	45	1,055
CDe/cde(FC)	5·0	245	16	333
CDe/cde(JB)	N.T.	N.T.	12	202
CDe/cde(II-10)	4·1	178	9·1	109
CDe/cde(III-2)†	3·8	185	8·3	111
CDe/Cde	1·5	128	4·0	12
cde/cde	negative	9	negative	negative

* 50 per cent endpoint titre = $1/HD_{50}$.
† Guinea-pig sera were absorbed with normal cde/cde cells.
‡ Individuals II-10 and III-2 are the mother and sibling of the Rh_{null} propositus, Mrs. E. M.

The quantitative relationship between the amount of D antigen on the cell and LW activity, indicated by the data, provides strong evidence that the specificities of LW antibodies are complementary to some portion of the structural configuration of D determinants. This is consistent with the observation that blocking D sites with incomplete anti-D does not reduce the LW reactions of the cell[6]. The parallelism of anti-LW assay curves found with cells of Rh genotypes which give assay curves of highly diversified slopes with anti-D sera[7] also suggests that LW and D antibodies are not attaching to identical sites on the D structure.

The observation that the mother and sibling of the Rh_{null} propositus have weak LW reactions comparable to their weak D reactions does not agree with the findings of Levine *et al.*[1] that their LW antigens are as strongly reactive as those of normal CDe/cde control cells. This is an important observation since quantitative studies[8] have confirmed that the D expression of these two family members have been suppressed, presumably by the same genetic mechanism which has caused the Rh_{null} condition of the propositus. The fact that the LW reactivities of these individuals are diminished concomitant with the suppression of their D reactivities is strong supportive evidence that LW antibodies are reacting with the D determinants of red cells.

In view of the above findings and the fact that Rh_{null} bloods, which are devoid of all detectable Rh substances, also lack LW antigens, the possibility that LW determinants may be associated with a portion of the Rh substance common to all normal Rh molecules should be re-examined. This theoretical possibility, suggested by Murray and Clark[9] as early as 1952, is attractive, since it provides reasonable explanations of all findings. The occurrence of LW negative individuals with normal Rh antigens, for example, can be explained by the absence of the LW determinants of the Rh molecule analogous to the absence of determinants from the Rh substances of –D–/–D–, cD–/cD– and C^wC–/C^wD– genotypes. The multitude of variants of Rh antigens already documented makes it most probable that some genetic alteration(s) exist which affect chemical groupings on Rh substance that are not directly involved in the C, D, E, c and e specificities of the molecule. The argument could be raised in opposition that the absence or modification of LW determinants on Rh molecules would not account for the LW negative phenotypes of D positive individuals if LW antibodies react with D determinants. The simplest explanation is that the chemical groupings on the large D structure which confer LW complementarity are absent in these individuals or their linkage to the D structure differs and the spatial orientation and geometry differ in consequence. The postulation that LW determinants are associated with Rh substance implies that LW is a product of Rh genes. However, by analogy with the presence of the products of independent Lewis genes

on A and B substances, these determinants could be the expression of independent LW genes.

Variation of Red Cell Acid Phosphatase in Two Species of Kangaroos

INHERITED variation has been recently demonstrated in the transferrin of an Australian marsupial, *Macropus rufus* (=*Megaleia rufa*)[1]. So far no other variation has been shown in the blood of this or other marsupials. The present communication reports the investigation of red cell acid phosphatase in two species of Australian marsupials, *M. rufus* and *M. giganteus*, the former commonly known as the red kangaroo and the latter as the grey kangaroo.

The animals used in the present study were kept in captivity at the C.S.I.R.O. Division of Wildlife Research, Canberra. Blood was collected by puncture of the caudal vein. The method for determining acid phosphatase patterns was that described by Hopkinson, Spencer and Harris[2] with minor modifications. The haemolysates were prepared by macerating clotted blood, washing the resultant cells three times with physiological saline and lysing them with an equal volume of distilled water. The haemolysates were stored at $-15°$ C until use. Horizontal starch-gel electrophoresis using thick filter paper inserts (Whatman No. 17) was carried out with a potential gradient of 5·5 – 6·0 V/cm for 16–17 h at $+5°$ C and at *p*H 6·0 (gel buffer: 0·005 M succinic acid and 0·0092 M *tris*, bridge buffer: 0·41 M citric acid/sodium hydroxide). The gels were prepared with an 8·5 per cent starch concentration rather than with the 9·7 per cent recommended by the manufacturers (Connaught Laboratory hydrolysed starch, lot 209–1). After electrophoresis the gels were sliced horizontally and placed in flat glass dishes with covers. The cut surfaces were then covered with a solution of 0·005 M phenolphthalein diphosphate in 0·05 M citrate buffer at *p*H 6·0 and incubated for 2–3 h at 37° C. After incubation the reagent was decanted and about 3 ml. of concentrated ammonium hydroxide poured over each gel. Red zones appeared in areas where phenolphthalein had been liberated from phenolphthalein diphosphate by acid phosphatase.

Twenty-six out of fifty-four red kangaroos showed a pattern which is tentatively called the 'K' type (Fig. 1, 1). This consisted of two components, and the faster was slightly smaller than the slower component. Both were oval in shape. Eighteen other animals showed the 'K' pattern but with an additional small zone of acid phosphatase which was found to be moving ahead of the faster component (Fig. 1, 2). This zone is probably due to some change in the protein during storage because it was not demonstrated in haemolysates of freshly collected blood samples from three of the animals that had previously shown it. Eight of the remaining ten red kangaroos showed a pattern different from the 'K' type. In this pattern two components migrating at the same rate as the components found in 'K' type were present but the faster was smaller and less intensely stained than the slower moving component (Fig. 1, 3). However, this changed pattern could not be reproduced in the haemolysates of freshly collected blood samples from two of the ten animals but instead a normal pattern of the 'K' type was observed. This seems to suggest that the alteration in pattern is probably due to changes during storage. No phosphatase activity was detected in the red cells of the remaining two kangaroos.

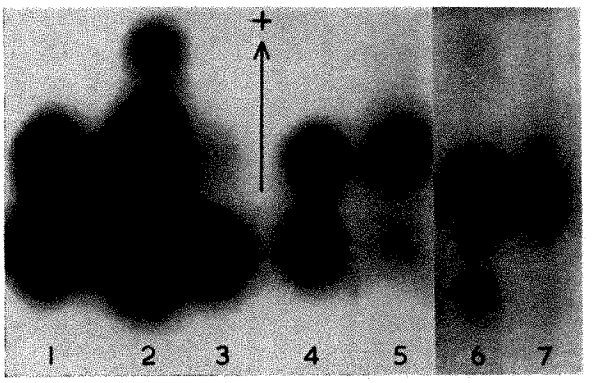

Fig. 1. Red cell acid phosphatase types found in red and grey kangaroos and some of the patterns found in man. The types are from left to right: 1, 'K'; 2, altered 'K'; 3, altered 'K'; 4, 'G'; 5, altered 'G'; 6, human B; 7, human BA

Eighteen grey kangaroos were examined and twelve showed a different pattern which is tentatively called the 'G' type (Fig. 1, 4). The two components in this type were of the same staining intensity and migration rate as the components of the 'K' type. However, the components were usually of equal size and were round in shape. Two grey kangaroos showed the typical 'K' type pattern and four showed an atypical 'G' type. In this atypical pattern there were two components with mobilities similar to the 'G' type components but the slower was less intensely stained than the faster moving component (Fig. 1, 5). This is also probably due to changes during storage and was not observed in two animals from which fresh samples were obtained.

The present work has shown difference in the pattern of red cell acid phosphatase in the two species of Macropods investigated. No evidence of polymorphism was found in the red species but the pattern was usually different from that of the grey species. Two distinct patterns were found in the grey animals and they are believed to represent a true polymorphism. Unfortunately, it was not possible to test this hypothesis because an insufficient number of animals with known pedigrees was examined.

The nature of the changes in electrophoretic mobility resulting from storage in a number of samples is being investigated. It is of interest that in the red species the fast component was presumably unstable and yielded a third area with enzymatic activity. In the grey species the slow component appeared to have deteriorated during storage.

I thank Prof. R. J. Walsh for his encouragement and interest in this work and Dr. G. B. Sharman for providing the blood samples.

Fibrinogen as a Co-factor in the Reaction of Platelets with Kaolin

WE have shown[1] that the clotting time of platelet-rich plasma (PRP) is progressively shortened by incubation at 37° C with a suspension of kaolin, and that this reflects a progressive increase in availability of platelet factor 3 (PF3) as well as activation of the plasma clotting system. Since maximal acceleration of clotting by kaolin was only achieved when platelets and plasma were activated together, it seemed likely that a plasma component was required for the reaction of platelets with kaolin. In order to determine whether a plasma coagulation factor was concerned in this reaction, investigations were carried out on the PRP of patients with a series of congenital coagulation defects. Equal volumes (0·1 ml.) of PRP and kaolin (5 mg per ml. of buffered saline, *p*H 7·3) were incubated at 37° C for 20 min and then recalcified with 0·1 ml. of 0·025 M calcium chloride, 0·1 ml. of a partially purified preparation of the deficient factor (or of buffered saline) being added in each case immediately before or after incubation with the kaolin. In the cases of factor-XII and factor-XI deficiency, activation product (prepared by the method of Nossel[2]) was used in place of the respective purified factors. Factors V and VIII were prepared by ammonium sulphate precipitation from barium sulphate-adsorbed platelet-poor oxalated normal plasma and factors VII, IX and X by adsorption of normal serum on to barium sulphate and subsequent elution into 5 per cent trisodium citrate. The fibrinogen reagent used (kindly provided by the Blood Products Laboratory of the Lister Institute) was prepared from fresh plasma by the method of Kekwick and Mackay[3] and was 66 per cent clottable; it also contained plasminogen and some factor VIII and anti-von Willebrand activity.

The results of this series of experiments are shown in Table 1, from which it can be seen that in every case, except those of fibrinogen deficiency, there was no significant difference between the degree of correction of the clotting time of PRP, whether the deficient factor was added before or after incubation with kaolin. It thus appears that the activation of PF3 by kaolin does not depend on prior activation of factors XII and XI, and is independent of all the clotting factors tested except fibrinogen. Horowitz[4], using a Stypven time system, has also found that factors V, VIII, X, XI and XII are not required for PF3 activation by celite.

In order to determine the quantitative relationship between fibrinogen and PF3 activation, PRP from the patient with a plasma fibrinogen concentration of 15 mg per 100 ml. was incubated for 20 min with an equal volume of kaolin suspension in the presence of a series of dilutions of fibrinogen; a mixture of equal parts of fibrinogen (310 mg per 100 ml.) and 0·025 M calcium chloride was then added, so that the clotting time of the mixture was not significantly influenced by the final fibrinogen concentration, but only by that present during incubation with kaolin. The results (Fig. 1) show that PF3 availability is significantly reduced only when the fibrinogen concentration falls below about 30 mg per 100 ml. This is in close agreement with the fibrinogen concentration of 20 mg per 100 ml. which Caen *et al.*[6], in investigations on the same patient, found necessary for spontaneous platelet aggregation and adhesion to glass.

Table 1. KAOLIN CLOTTING TIME OF DEFICIENT PLATELET-RICH PLASMA

Deficient factor	(Per cent)	Clotting time (sec) Deficient factor added before incubation with kaolin	Deficient factor added after incubation with kaolin	Deficient factor not added

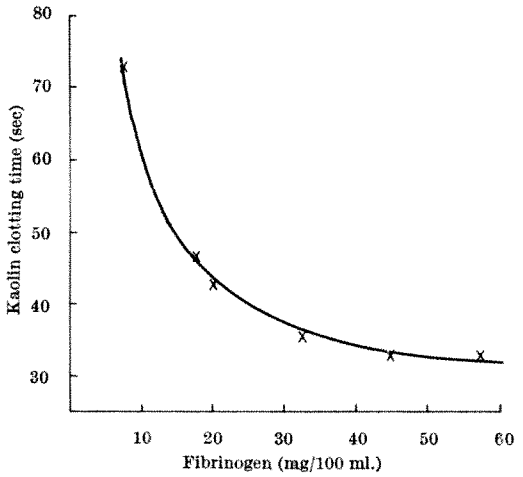

Fig. 1. Relationship between kaolin clotting time of platelet-rich plasma and fibrinogen concentration during incubation with kaolin

Evidence has also been presented[7–9] that fibrinogen is an essential co-factor for the aggregation of platelets by adenosine diphosphate (ADP). We have found that the activation of PF3 by incubation of PRP with kaolin is always associated with the formation of mixed aggregates of platelets and kaolin particles, and that both are inhibited by ADP antagonists and by EDTA, and fail to occur in thrombasthenia[1,10,11]. Platelet/kaolin aggregation also failed to occur during the investigations on afibrinogenaemic PRP reported here, unless fibrinogen was added. These findings thus suggest that PF3 availability in this system results from the adhesion of platelets to kaolin and from their aggregation, and that these reactions are dependent on the action of ADP, which here, as in other systems which have been investigated, requires fibrinogen as a co-factor.

These experiments do not, of course, resolve the question whether other plasma components besides the coagulation factors are also required for this reaction. Similar investigations on patients with von Willebrand's disease have given inconclusive results, chiefly for the reason that the kaolin clotting time of their PRP has usually differed too slightly from that of normal controls to allow the effect of plasma fractions to be properly evaluated.

We are grateful to the various physicians who have allowed us to study their patients, and particularly to Drs. J. P. Caen and E. Gugler, who also put their laboratories at our disposal. This work was supported by a grant from the Medical Research Council.

IMMUNOLOGY

Synthesis of Antibody *in vitro* by Lymph Node Fragments using Absorbable Gelatin Sponges

It has been conclusively demonstrated that fragments of lymph nodes obtained from previously immunized rabbits can be secondarily stimulated *in vitro* with the specific antigen[1,2]. Richards *et al.*[3] and Richardson[4] have shown that the antibody released by fragments *in vitro* is actually synthesized *de novo*. In the main, glass wool pads have been used to support the fragments in the culture. Unfortunately, the use of glass wool pads impairs histological investigation of the fragments during antibody synthesis. The glass wool cannot be sectioned on a microtome so that any fragment studied must be removed from the pad, resulting in loss of the periphery of the fragment which clings tightly to the glass wool. The cells which migrate from the tissue into the interstices of the pad are also not available for histological study. An ideal supporting medium for combined histological and antibody studies should be capable of being sectioned so that the cells can be observed in their relationships to each other and to the supporting medium. In order to pursue this type of investigation, we decided to investigate the possible use of absorbable gelatin sponges, as a replacement for the glass wool.

Young, adult New Zealand rabbits were immunized with rat serum albumin (RSA) (prepared by ammonium sulphate fractionation of whole rat serum, pure by the criterion of immunoelectrophoresis) and bovine serum albumin (BSA) (obtained from Pentex Incorporated, Kankakee, Illinois). The rabbits were given three intravenous injections of antigen (20 mg per injection) and three foot pad injections, bilaterally (10 mg per foot pad per injection) over a period of 10 days. All injections were made in saline. After a period of 3–4 months, during which time the serum antibody titre decreased to a low level, the rabbits were killed by intravenous administration of pentothal (50 mg per kg body weight) and the popliteal lymph nodes were excised within a period of 5 min. The nodes were trimmed of excess fat and cut into fragments of about 1–2 mm^3 in sterile Hanks's solution (obtained from Difco Laboratories, Detroit, Michigan). Six to eight fragments were placed into each Leighton tube and either a glass wool pad or absorbable gelatin sponge ('Gelfoam', Upjohn Co. of Canada, Montreal) was then overlaid. The fragments were then incubated, at room temperature for 2 h, with 0·5 mg of the antigen in 1 ml. Eagle's medium (HeLa, ten times, obtained from Difco Laboratories) containing fresh normal rabbit serum (20 per cent), glutamine (0·04 per cent), sodium bicarbonate (0·135 per cent), streptomycin (50 μg per ml.) and penicillin (100 u./ml.)[1,2]. The fragments in the control tubes were incubated with the modified Eagle's medium only. The fragments were then washed three times with aliquots of the medium and incubated with 1 ml. of medium at 37° C. The medium was changed every 3 days and tested for the presence of antibody by the tanned cell haemagglutination technique[5].

Table 2. Synthesis of Antibody to Bovine Serum Albumin *in vitro* using Glass Wool Pads and Absorbable Gelatin Sponges

Table No.	BSA incubated with fragments	Type of support used	Antibody titres* of supernatants in days of culture 6	9	12	15	18
1		Glass	320	640	320	320	40
2	–	wool	20	0	0	0	0
3			160	320	160	160	40
4		Glass	40	640	640	640	160
5	+	wool	40	320	1,280	640	80
6			40	320	640	320	160
7		Gelatin	0	0	0	0	0
8	–	sponge	0	0	0	0	0
9			0	0	0	0	0
10		Gelatin	0	0	0	20	0
11	+	sponge	0	80	320	320	40
12			0	80	160	80	80

* Titres less than 10 are consicered to be negative.

As can be seen from Tables 1 and 2, the gelatin sponges functioned at least as well as glass wool pads in the facilitation of the immune response *in vitro*. In point of fact, the sponges appeared to act in a more discriminate fashion in the presence of BSA (Table 2) since the control tubes with gelatin sponges contained no detectable antibody whereas the control tubes with glass wool pads invariably contained antibody, but in much lower titre than the experimental tubes.

In summary, it has been demonstrated that absorbable gelatin sponges can replace glass wool pads in the maintenance of antibody-forming lymph node fragments *in vitro* without any adverse effect in so far as the peak titre of antibody formation is concerned or with respect to the temporal aspects of the *in vitro* antibody formation curve. The utilization of gelatin sponges should facilitate histological examination of the fragments since they can easily be fixed and sectioned, properties which are not possessed by glass wool.

Cytotoxic Effects of Antisera against Dye–Protein Complexes

It has been shown in rabbits that antibodies are formed following immunization with dye–protein complexes. These antibodies react with stained cells and reveal a cytotoxic activity in the presence of active complement[1,2]. Sulphorhodamine *B* was coupled to bovine albumin according to Uehleke[3]. Rabbits were immunized with this dye–protein complex and an antiserum (DPC-antiserum)

* Antibody titres less than 10 are considered to be negative.

was obtained which gave a positive reaction in Landsteiner's inhibition test. Cytotoxic activity was assayed in different systems.

(1) Sulphorhodamine *B*-stained cells of Ehrlich's ascites tumour (stained EAC) of the mouse; addition of DPC-antiserum to stained EAC produces cytotoxic changes[1,2]. A similar effect is obtained by addition of specific antisera against EAC[1]. Normal rabbit's serum does not reveal such activity.

(2) Solid Ehrlich's tumours stained intravitally with sulphorhodamine *B*; characteristic necroses occur after intratumoral injection of DPC-antiserum. These necroses differ significantly from spontaneous necroses[1,2]. In this assay normal rabbit's serum is inactive.

(3) Cytotoxic effects of DPC-antisera on stained HeLa cells in tissue culture; HeLa cells were cultivated in bottle cultures (medium: Gey's solution with addition of 10 per cent cord serum, 0·25 per cent lactalbumin, 'neomycin' and penicillin) and transplanted in bottles with mounted cover-slides. Staining of cells was performed by adding 1 ml. of sulphorhodamine *B* (1 : 5,000) to 9 ml. of culture medium. 24 h later, the cultures were washed with Gey's solution. In the assay, 1 ml. Ringer's solution (zero-control), 0·5 ml. DPC-antiserum and 0·5 ml. active complement or 0·5 ml. normal rabbit serum and 0·5 ml. active complement, respectively, were added to 9 ml. of the culture medium. The changes of the cultures were regularly controlled. At different intervals cover-slides were withdrawn, fixed in alcohol and stained with iron-haematoxylin. Fig. 1 shows HeLa cells stained with sulphorhodamine *B* after addition of normal rabbit serum. Fig. 2 shows the same cells after addition of DPC-antiserum. A comparable cytotoxic effect is produced by addition of specific anti-HeLa cell serum prepared according to McAllister *et al.*[5].

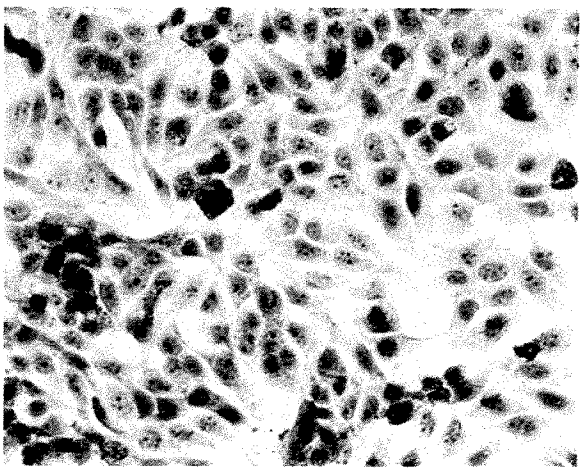

Fig. 1. Effect of normal rabbit's serum and active complement on sulphorhodamine *B*-stained HeLa cells in tissue culture (4 h)

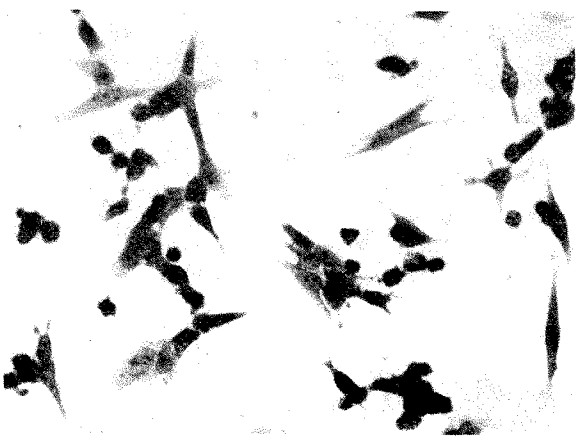

Fig. 2. Effect of DPC-antiserum and active complement on sulphorhodamine *B*-stained HeLa cells in tissue culture (4 h after addition)

The results demonstrate the possibility of producing a cytotoxic effect with a non-cytotoxic serum and a non-toxic dye as a hapten. It is necessary, however, that the cells have bound the dye and that the serum contains antibodies against this component.

HISTOCHEMISTRY

Histochemical Observations on the Lipids of Sound Human Dentine

EVIDENCE for the presence of lipids in sound human dentine has indicated that they are present in the dentinal tubules[1], though, following an unmasking treatment with hot pyridine, they also have been observed in the matrix, at the junction of dentine and predentine[2]. This communication reports on the use of other unmasking techniques, combined with various histochemical stains, to investigate further the lipid components of this tissue.

Undecalcified ground sections of dentine, approximately 7μ thick, were prepared from fresh and fixed non-carious human molar and pre-molar teeth. Fixation was in 10 per cent neutral formol saline, or 7 per cent ethyl alcohol. Sections were stained, without previous treatment, or following one of a series of progressively intense unmasking techniques. These consisted of 0·02 N hydrochloric acid alone, or followed by water at 20° C, 60° C or 100° C, or alternatively 0·02 per cent acetic or trichloracetic acid at 60° C or 100° C, each for wide ranges of time. Following etching in 0·02 N hydrochloric acid at 20° C for 1–2 min, sections were also treated with 1 per cent sodium ricinoleate, 0·1 per cent trypsin, or chymotrypsin, 1 mg/ml. collagenase, hyaluronidase or phospholipase *D*, each in the appropriate buffer, at 37° C for 2–4 h, then washed in running water at 20° C for 24 h (ref. 3). Following these unmasking procedures the sections were stained by one of the following methods: acetone-Sudan black *B*[3], acetone-acetylated Sudan black *B*[3], osmium tetroxide vapour[4], Nile blue sulphate[5], phosphomolybdic acid[6], or Luxol fast blue[7]. Some sections, stained with Sudan black *B*, were extracted with many different solvents at 20° C and 60° C, and also in 3 : 1 methanol : chloroform, in a Soxhlet extractor, for periods up to a hundred days, then restained. Similar stained sections were also decalcified and mounted in a watery medium, or alternatively dehydrated and mounted in balsam. Contact microradiographs were obtained of some sections prior to staining, to relate the development of calcification to the staining results, and comparable sections were incinerated in air at 600° C.

In untreated sections, only the contents of the dentinal tubules and any uncalcified peritubules matrix around them; stained by these methods, however, progressively more intense unmasking, from brief etching to boiling acetic acid (8 min), revealed a changing picture. The peritubular dentine matrix (that is, any matrix arranged

around, as distinct from between, the tubules), adjacent to the predentine, was the first to stain heavily, and as the intensity of the unmasking was increased, so the peritubular matrix in the more peripheral dentine was stained. However, a zone adjacent to the enamel failed to stain under all circumstances. With more prolonged and intense unmasking, the zone adjacent to the predentine, which had stained in the first instance, failed now to do so Thus, including the predentine, four zones became discernible, numbered 1 to 4, from the pulp. Zone 3 was reduced in size in radicular dentine, so that in the apical third it was absent, and in the middle third it was seen, in transverse sections, as two crescents, labial and lingual. The junction between zones 2 and 3 was seen to coincide with the calcification of the peritubular matrix, which then became hypercalcified, as seen on the microradiographs. The very intimate relationship between the organic and inorganic fractions of the dentine matrix was illustrated in incinerated sections where carbon (identified by electron-spin resonance) was retained in the hypercalcified peritubular matrix of zone 3, and mirrored in part the appearance of a stained section.

The extraction of the lipids from the dentine matrix was extremely difficult, 75–100 days' extraction being necessary to prevent subsequent restaining. The soap and enzymes employed failed to unmask the lipids under these conditions, and complete decalcification of a dentine section resulted in subsequent diffuse and faint staining. When an undecalcified section was stained satisfactorily with Sudan black *B*, then decalcified and mounted in a watery medium, apart from some shrinkage little change was observed. However, after passing such a section through alcohol and xylene, and mounting in balsam, all the stain was removed other than traces around the tubules.

The positive results obtained with the stains employed indicate the presence of choline-containing phospholipids (probably lecithins) in peritubular dentine matrix. These are in such intimate relationship with both the organic and inorganic fractions that some disorganization of the tissue is necessary to unmask these elements. However, more intense treatment such as complete decalcification results in their loss. For these reasons dentine sections have been stained as thin hard sections, the surfaces of which have been disorganized to some degree, while the centre acts as a reservoir for the components.

RADIOBIOLOGY

Are Iodotyrosines Normal Constituents of Plasma?

The question of whether or not the iodotyrosines exist normally in the circulation has been the subject of considerable experiment and discussion during the past seven years, beginning with a report by Werner and Block[1] that they detected iodine in the iodotyrosine areas of chromatograms of serum from human subjects. Some subsequent investigations have provided supporting evidence while others have not[2–6]. Experimental evidence has not led to a satisfactory answer to the basic question because the concentrations of circulating iodine-containing substances are so low and a variety of artefacts may arise as a result of manipulations during the analysis[7]. In addition, not all assumptions inherent in present methods have been subject to direct substantiation. The extent of breakdown of iodotyrosines prior to analysis is unknown; added tracers may not behave as the native substances due to differences in protein binding; and these substances may not be principally contained in the plasma, which has been the only fraction of blood investigated by most research workers. Consequently, the conclusion accepted at present is only conditional: if mono- and di-iodotyrosine are normally present, they are probably protein bound and do not occur in significant amounts as free substances in normal plasma samples[8].

Thermal neutron activation analysis[9,10] or mass analysis[11] of iodine-129 increases the sensitivity of iodine analysis by a factor of at least a thousand over other methods. Replacing the natural iodine of the body with this isotope allows applications of this increased sensitivity of detection to the quantitation of iodine in biological samples[12]. It appeared feasible to study extrathyroidal iodine metabolism with the same analytical power previously used in the investigations of intrathyroidal iodine metabolism because this increase in sensitivity approximates the ratio of thyroidal to extrathyroidal iodine concentration. Our first step was to attempt to measure the circulating iodotyrosines.

Rats were maintained for 3–6 months on a diet which supplied daily 5–7 μg of iodine, 86 per cent of which was iodine-129. Samples were obtained by pooling the plasma of six such rats. 5 or 10 ml. portions were taken for analysis. Iodine-131-labelled carriers of mono- and di-iodotyrosine, triiodothyronine and thyroxine (hereafter referred to, respectively, as MIT, DIT, T-3 and T-4) were added to the portions. The iodoamino-acids were then extracted into hot *n*-butanol, concentrated, and chromatographed in 2-butanol–3 per cent ammonia (3 : 1) by the procedure used by Block *et al.*[13]. The separated iodoamino-acids were identified by autoradiography. Each spot was removed from the chromatograph and rechromatographed in a second solvent—*n*-butanol–dioxane–3 N ammonium hydroxide (4 : 1 : 4)—to assure the purity of the specific iodo compounds. The spots from these paper chromatograms which contained the doubly purified substances were placed in quartz vials, sealed under vacuum, and irradiated for 16 h in a thermal neutron flux of approximately 10^{13} n/cm²/sec. The vials were then broken and dropped with their contents into a few millilitres of 0·5 per cent sodium hydroxide containing 20 mg of carrier iodide. The radiation damage to the chromatographic paper made it soluble in the dilute sodium hydroxide. The iodine was separated by the distillation procedure of Bowen[14] and any residual activity due to radiobromine removed by extraction with hydroxylamine according to the procedure of Cosgrove *et al.*[15]. The iodide thus purified was precipitated as silver iodide and counted in a 3 in. × 3 in. thallium-activated sodium iodide crystal. The γ-ray spectrum and the half-life of each sample were determined to assure that radiochemical purity had been achieved. After the iodine-130 activity had decayed, the iodine-131 activity was compared with the activity of the original carrier chromatograms. This allowed for the calculation of an overall yield of the procedure for each sample. Standards of iodine-129-labelled DIT were analysed at the same time.

Control experiments consisted of adding labelled iodide, or one of the labelled iodoamino-acids, together with non-labelled carriers of the other iodoamino-acids and processing the plasma by the foregoing procedure. Some control experiments were done without the addition of the non-labelled carriers. The distribution of label on these was determined. We found no evidence of exchange reactions or of coupling of the iodotyrosines to form thyronines or of breakdown of the thyronines into iodotyrosines. Some deiodination occurred during chromatography, but this was corrected for in the yield calculation. The

alteration of the tracer activity due to the neutron exposure was less than 1 per cent.

The results are summarized in Table 1. MIT and DIT iodine was found in all samples analysed. The amount ranged from 0·006 to 0·01 μg per 100 c.c. of pooled rat plasma samples. This was equal to between 1 and 2 per cent of the value obtained for thyroxine iodine.

Table 1. IODOAMINO-ACID COMPOSITION OF RAT PLASMA DETERMINED BY NEUTRON ACTIVATION ANALYSIS OF IODINE-129 IN PAPER CHROMATOGRAMS OF THE *n*-BUTANOL EXTRACT OF POOLED PLASMA FROM RATS IN ISOTOPIC EQUILIBRIUM WITH THIS ISOTOPE

Sample	Micrograms iodine per 100 c.c. plasma Pooled sample 1 (6 rats)	 Pooled sample 2 (6 rats)
MIT	0 008	0·006
DIT	0 007	0·010
T-3	0·177	0 065
T-4	0 916	0·999
Total	1·108	1·080

Since both iodine-129 and iodine-131 are fission products, we had to assume that the iodine-131 carriers might be contaminated with iodine-129 as this would result in a significant blank. Due to the great differences in half-lives of iodine-129 and iodine-131, the relative amount of iodine-129 would increase as the carrier solutions aged. 5 ml. portions of plasma from individual rats were processed after the carrier solutions had aged 28 days. Blank samples for the activation analysis procedure were prepared by adding iodine-13-labelled carrier to the areas just above and below the MIT and DIT spots on the final paper chromatograms. Because of the age of the carriers and the decreased volume of plasma (5 ml. compared with 10 ml.), the blank would contain a relatively greater amount of iodine-129 than in the experimental runs. The results are summarized in Table 2. In all three control experiments, the iodine-129 content of the iodotyrosine spot was greater than either of the two adjacent control areas.

Table 2

Sample	Micrograms iodine per 100 c.c. plasma
Rat 1, 5 c.c. plasma	
Blank (above)	0·001
MIT	0·004
Blank (below)	0·001
Rat 2, 5 c.c. plasma	
Blank (above)	0 003
MIT	0 008
Blank (below)	0·001
Rat 3, 5 c.c. plasma	
Blank (above)	0·001
DIT	0·006
Blank (below)	0·001

The iodine-131 used contained a trace of iodine-129 which resulted in a non-zero blank. By adding the iodine-131 labelled carrier to the areas just above and below the MIT and DIT spots on the final paper chromatograms and analysing for iodine-129, it was shown that MIT and DIT iodine was greater than the blank.

We have concluded that the iodotyrosines are normally present in the circulation of the rat. Because blank values were not subtracted from the original values, the results reported may contain as much as a 10 per cent positive error. Substitution of iodine-125 which is not fission produced as the tracer and other alterations of the procedure are in progress which should allow even more precise quantitation of these substances. Some experimental evidence has been obtained which suggests that the iodotyrosines concentrations in plasma may decrease with time after the samples have been removed from the animals. Also we have found, by iodine-125 isotopic equilibrium studies, that a significant portion of the circulating iodine is contained in the non-plasma portion of the blood.

This work was supported in part by a grant from the U.S. Public Health Service. We thank E. U. Buddemeyer and A. Karmen for their advice.

Inhibition of Oxygen Consumption of Liver Homogenates from Mice injected with Radioprotectors in the Presence of Pyruvate

FOLLOWING the working hypothesis put forward by Bacq and Alexander[1] according to which the 'chemical shock' induced by the injection of radioprotectors, at radioprotective dose, must have some importance in the mechanisms of action of these substances, we have measured the oxygen consumption of liver homogenates of mice injected with a dose of radioprotector when pyruvate was offered as substrate.

Preliminary experiments by one of us[2] have shown that after intravenous injection of cystamine (2 hydrochloric acid, 170 mg/kg), the largest decrease of oxygen uptake was observed with livers from mice killed 20 min after the injection (Table 1). There is no question about the nature of the metabolic upset: the decreased pyruvate utilization with accumulation of ketoacids points to an inhibition at the first metabolic step.

The following facts confirm and extend these findings. (*a*) The inhibition is already evident in the animal 10 min after an intraperitoneal injection of cystamine (Table 1). (*b*) The intravenous injection of mercaptoethanol (156 mg/kg) does not result in inhibition of respiration in the same conditions when the liver is taken 20 min after injection. Mercaptoethanol has no radioprotective action[3]. (*c*) This inhibition of oxygen consumption in the presence of pyruvate is not a specific action of sulphur-containing radioprotectors since the same phenomenon has been observed with livers of mice killed 20 min after

Table 1. OXYGEN CONSUMPTION (μl./h/10 mg DRY WEIGHT) BY SWISS MOUSE LIVER HOMOGENATE IN PRESENCE OF 50 μMOLES OF PYRUVATE
Effect of cystamine (2 hydrochloric acid, 170 mg/kg)

Controls	Time between intravenous injection and killing				Controls	Time between intraperitoneal injection and killing	
	3 min	10 min	20 min	30 min		3 min	10 min
21·4 ± 2·24	11·3 ± 2·33 0·02 > *P* > 0·01	15·2 ± 1·5 0·05 > *P* > 0·02	13·7 ± 1·4 *P* < 0·01	13·8 ± 2 01 0·02 > *P* > 0·01	20·66 ± 1·44	19·6 ± 1·60	13·7 ± 3·6 0·02 > *P* > 0·01

The main cavity of each Warburg vessel contained 2 8 ml. of a 1 : 10 (w/v) liver homogenate in the following medium: sodium chloride, 130 mM; potassium chloride, 12·8 mM; magnesium sulphate, 0 65 mM; phosphate buffer *p*H 7·4, 5 mM; the side-arm of each vessel contained either 0·2 ml. (50 μmoles) of a pyruvate solution or 0·2 ml. of Ringer's solution. The oxygen consumption due to pyruvate was equated to the difference between the oxygen uptake in the presence and absence of added substrate.

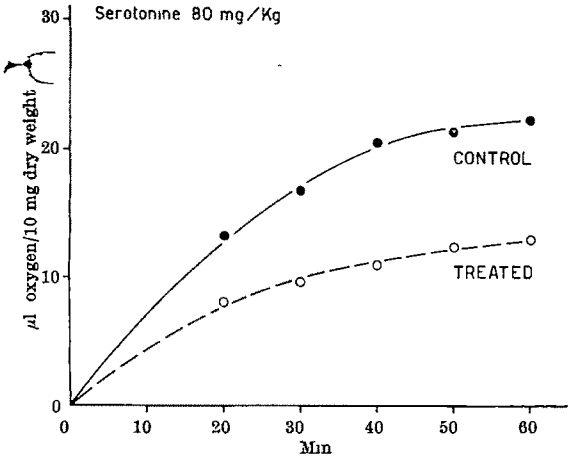

Fig. 1. Oxygen consumption of Swiss mouse liver homogenates in presence of pyruvate; same experimental conditions as in Table 1. The animals were killed 20 min after they had been injected intravenously with serotonin

injections of serotonin (80 mg/kg, Fig. 1). The radioprotective action of this amine is well known.

BIOLOGY

Some Experiments on the Nutrition of Plants growing on Coal Mine Waste Heaps

COLONIZATION of abandoned pit heaps in Britain begins after a few years with the appearance of scattered grasses and herbs which gradually spread until eventually they form a more or less complete cover. At some stage during the development of this grass/herb community, shrubs and trees begin to colonize the heaps and these in turn spread until after a period of from thirty to a hundred years closed woodland may be formed[1].

Ecologists who have examined this process have tended to concentrate attention on the initial stages of colonization and to stress the importance of the lack of surface stability and drought as the environmental factors which control colonization (see, for example, Rees[2] and Brierley[3]). While there is no doubt that these factors are important, especially in the early stages, there is little published information concerning the role of other factors, such as nutrition, or of the factors which control the nature and productivity of the vegetation once the surface has been stabilized and other physical factors have been ameliorated. This report describes some experiments which were designed to reveal whether mineral nutrition plays any part in pit-heap ecology.

There is some indirect evidence from other sources which suggests the importance of nutrition. It has been recognized for a long time by those concerned with the reclamation of industrial wastelands that pit heaps are very infertile[4] and that it is almost impossible to establish a plant cover on heaps without adding fertilizers. Also, it has been observed that pit-heap vegetation may tend to be calcicole or calcifuge, depending on the acidity of the particular heap. This suggests that nutrition may be important because it has been shown for other situations[5-7] that calcicole and to some extent calcifuge[7] behaviour depends on nutritional factors.

Our first experiment involved a laboratory assessment of the nutritional status of a large number of contrasting pit-heap soils. In the experiment a number of typical pit-heap species were grown from seed on the different soils in a growth cabinet at 17° C. The soils were treated with different nutrient solutions and after 5 weeks the plants were harvested, dried and weighed. Every pit-heap soil we examined, including freshly exposed and weathered, burnt and unburnt shales with *p*H values of from 3·2 to 7·8, was severely deficient in phosphorus and nitrogen. However, the response to phosphorus or nitrogen depended on the particular species and the acidity of the soil. Some typical results are given in Figs. 1 and 2. *Deschampsia flexuosa*, which is only found on heaps with acid soils, responded to added phosphate when it was grown on the acid soil (Fig. 1). When the soil was limed to a *p*H of about 6 it responded even more to added nutrients, possibly because of an effect of the *p*H on nutrient

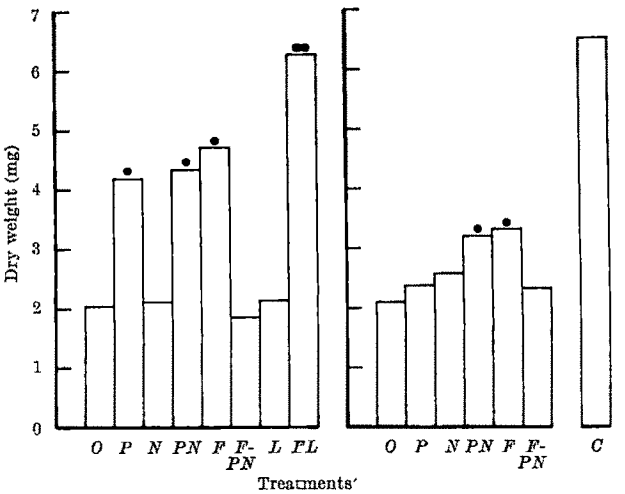

Fig. 1. Dry weight of *Deschampsia flexuosa* produced in 5 weeks on two pit-heap soils of different *p*H with various nutrient treatments. Left, unburnt shale, *p*H 3·2. Right, burnt shale, *p*H 7·4. Nutrient treatments based on Hewitt (ref. 8) applied weekly as follows, treatment *O*, watered with distilled water, *P* watered with solution containing 9 p.p.m. phosphorus as 'AnalaR' $NaH_2PO_4.2H_2O$, *N* solution containing 140 p.p.m. nitrogen as 'AnalaR' potassium nitrate; *PN*, solution containing both *P* and *N* as above; *F*, Hewitt (ref. 8) solution containing all major and micro-elements, *F-PN*, Hewitt solution minus *P* and *N*, *L*, treated with lime to a *p*H of about 6; *F+L*, Hewitt solution and limed; *C*, growth of *Deschampsia* on a control soil. Yields marked ● significantly (1 per cent level) different from unmarked yields. Yields marked ●● significantly (1 per cent level) different from those marked ●

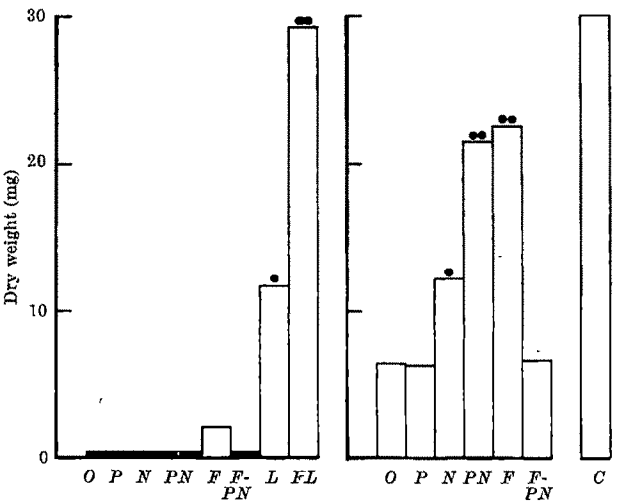

Fig. 2. Dry weight of *Plantago lanceolata* produced in 5 weeks on the same soils as in Fig. 1. Treatments as for Fig 1, except that *C* = growth of *Plantago* on a control soil

availability or to alleviation of a metal toxicity. The latter possibility is suggested because toxic levels of aluminium, manganese and iron are known to occur in many acid soils[5,9]. On the soil with a high *p*H (7·4) *Deschampsia* again responded to nutrients but the effect was much smaller and less clear cut. The performance of *Plantago lanceolata*, a species which is found only on less acid heaps and heaps with high *p*H, on the same two soils as were used in the *Deschampsia* experiment provided an interesting comparison (Fig. 2). It was impossible to keep the seedlings of *Plantago* alive on the acid soil unless it was limed. When it was limed, then there was a pronounced response to nutrients. *Plantago* responded to added nitrate on the soil with the high *p*H (7·4) but showed an even greater response when phosphate was supplied with the nitrate. The two species showed markedly contrasting behaviour on the two soils. We have some evidence that the poorer performance of *Plantago* compared with that of *Deschampsia* on the acid soil and the necessity for a prior liming of the soil before significant growth occurred may have been due to greater susceptibility of *Plantago* to a metal toxicity. If this proves to be the case, the situation is clearly very similar to that described by Rorison[5] for the growth of calcifuges and calcicoles on an acid soil. As yet we can advance no reasons for the difference in performance of the two species on the soil with the high *p*H.

Field experiments have been concerned with the effects of nutrition on seedling establishment and on the growth and productivity of established vegetation.

In the experiments on seedling establishment, batches of seeds of various species were sown in May in 20 cm² plots at the same sites previously assayed in the pot experiments. Plots were given different nutrients applied as 'AnalaR' chemicals in powder form and the numbers and appearance of seedlings were recorded at intervals over the next 7 months. Table 1 gives some records for *Plantago lanceolata* at three sites. It is clear that at the time of writing the nutrient treatments have had no effect on establishment but have had an enormous effect on the growth of the seedlings (Fig. 3).

Finally, the results of one of the field experiments on the effects of nutrients on established vegetation are given in Table 2. An area with a fairly uniform and well-established sward of *Agrostis tenuis* was chosen and 1 m² plots were marked out on it in a randomized block design. Three nutrient treatments were applied as 'AnalaR' chemicals in powder form in June, then 4 months later the vegetation of each of the plots was cropped. Cropping consisted of removing shoots and leaves just above ground-level with a pair of shears. The harvested vegetation was sorted into living and dead material before being dried and weighed. There was a massive increase

Fig. 3. Silhouettes of *Plantago lanceolata* plants taken from plots after seven months growth in a field experiment. Left, no nutrient treatment. Right, plot treated with nitrogen, phosphorus, potassium and magnesium, and limed at sowing time

in the growth and productivity of the vegetation to which nutrients had been added. In addition, the combination of liming and nutrients resulted in a considerable reduction in the amount of dead material present in the plots. This might have been due to an effect on the senescence of leaves (both phosphorus and nitrogen deficiency accelerate senescence[10]) and to a faster decay rate of dead material.

In conclusion, the foregoing experiments suggest that the vegetation of pit heaps is greatly influenced by nutritional factors. Because physical factors, such as surface stability, have previously been shown to be important, a considerable ecological problem is posed, namely, the estimation of where, when and to what extent different factors affect the vegetation of a particular pit heap.

Pesticide Residues in the Irish Environment

IN recent years there has been some public concern regarding the extent to which pesticide residues are found in wild-life. The existence of environmental contamination by pesticides in Britain has been recognized by the Advisory Committee on Pesticides and Other Toxic Chemicals[1]. The Crop Husbandry and Crop Protection Department of the Agricultural Institute, as part of its programme, has been keeping this problem under review. Accordingly, an investigation of the occurrence and distribution of residues of organic mercury and the organic chlorine insecticides, lindane (γ-BHC), aldrin, dieldrin and *pp'*-DDT, in the Irish environment was undertaken. Because of the maritime nature of the country and its position on the western edge of Europe, the findings should be of particular interest.

Samples for chemical analysis were received from the Veterinary Research Laboratory and the Fisheries Division of the Department of Agriculture and Fisheries, the

Veterinary College of Ireland, and members of the public. With the exception of the birds' eggs, all the specimens submitted were from species either found dead or moribund, some in circumstances suggestive of possible pesticide poisoning.

The specimens were analysed for organic chlorine residues using the extraction and 'clean-up' method of de Faubert Maunder *et al.*[2], followed by the gas-liquid chromatographic procedure detailed by Dimick and Hartmann[3]. Organic mercury residues were determined by the method described by Gage[4]. The lowest levels detectable were 0·002 p.p.m. aldrin, 0·01 p.p.m. lindane, dieldrin and *pp'*-DDT, and 0·015 p.p.m. organic mercury.

The results of the analyses, which were carried out in 1964 and 1965, are summarized in Tables 1 and 2.

The organs and tissues of one foxhound, eleven pheasants, one kestrel, two thrushes, three pigeons, one bullfinch, four salmon and three trout were examined (Table 1). Organic chlorine residues, principally dieldrin, were found in twenty-one out of the twenty-six specimens analysed. In addition, two pheasants and the three pigeons contained organic mercury residues. Death in these cases could be attributed to pesticide poisoning. The high concentration of dieldrin (13·89 p.p.m.) in the breast muscle of one pheasant probably caused the death of this bird. In the pathological examinations which were carried out by the Veterinary Research Laboratory, Abbotstown, County Dublin, enteritis was observed in all six fatalities. This is in accord with the possibility of death occurring from organic chlorine poisoning[5].

It was later established that river pollution was responsible for the three trout mortalities and it was suggested that the four salmon fatalities were due to a cold water form of columnaris disease caused by a myxobacterium *Cytophaga* (s. *Chondrocuccus*) *columnaris*[6], but this has not been confirmed.

Thirty-one birds' eggs collected from three sites in 1965 were analysed (Table 2). The mallard, guillemot, fulmar, razorbill and kittiwake eggs were all obtained from the Great Saltee Island, County Wexford, which lies at the junction of St. George's Channel and the Atlantic. The presence of organic chlorine residues in guillemot, kittiwake and shag (*Phalacrocorax aristotelis*) eggs collected from this site in 1964 has already been reported[7]. The levels of the residues present in the 1965 eggs did not prevent development of the embryos, as most of the eggs were in various stages of incubation at the time of analysis. The residues in the mallard eggs were considerably lower than those in the guillemot, fulmar, razorbill, and kittiwake eggs, which were nearly all of the same order. These sea birds, which range more widely than the mallard, possibly fed on molluscs and fish in waters already contaminated with organic chlorine residues. Moore and Tatton[7] have suggested that the eggs of sea birds might be useful indicator organisms for detecting changes in environmental contamination by persistent pesticides.

The results show that low levels of organic chlorine residues are present in a wide variety of biological material. The possibility that these residues are due to industrial contamination by Irish sources seems very remote. Relatively few fatalities may be definitely attributed to the organic chlorine insecticides. The work is being continued.

I thank Mr. C. B. Adams and the Veterinary Research Laboratory, Abbotstown, County Dublin, for the pathological examinations of the bird fatalities, Dr. A. E. J. Went, of the Fisheries Division of the Department of Agriculture and Fisheries, for the salmon samples, Mr. D. Cabot, University College, Galway, for the mallard and sea birds' eggs, other donors for specimens, Miss C. Kenna, Miss J. Oliver and Mr. J. O'Shea for technical

Occurrence of Mesoplastra in a Cryptodiran Turtle, *Lepidochelys olivacea*

MESOPLASTRAL bones, a characteristic feature of most amphichelid turtles, are to-day restricted to members of the Pleurodiran family Pelomedusidae. Of the three genera of this family, two (*Podocnemis* and *Pelomedusa*) have the mesoplastra reduced to small, widely spaced bones separating the hyoplastra and hypoplastra at the outer part of their common suture. Only in *Pelusios* are they retained in their pristine contiguous condition, a retention perhaps connected with the necessity of the hyoplastra having a straight posterior margin to allow flexure of the hinged plastron to occur. The mesoplastra of *Pelomedusa* may be missing as an occasional variant[1], but there appears to be no record of mesoplastra having been recorded in a cryptodire; indeed, a fossil plastron with mesoplastra would definitely not be classified as cryptodiran at all. It is therefore of interest to record the finding of a plastron of the Pacific ridley (*Lepidochelys olivacea*) in which the hyo- and hypoplastra appear to be separated by a pair of well-defined contiguous mesoplastra (Fig. 1). The plastron was found separate from the remainder of the animal on Shell Beach, North-West District, British Guiana. (The discovery of *Lepidochelys* in British Guiana is documented elsewhere[2,3].) The specimen was not collected, but a colour slide was taken of it, close inspection of which leaves no doubt that the breaks are true sutures and not sulci or post-mortem fractures.

It is possibly significant that the specimen involved should be a *Lepidochelys*, as the Cheloniidae are closer to the Amphichelydia than any other turtle family, judging by such features as the retention of infra-marginals and other small plastral laminae (though the non-retractile neck and roofed-over skull are probably secondary reversions). Moreover, the ridley is the most primitive member of the family, having the most highly ossified shell, and showing a curious reversion to a (supposedly primitive) multi-scutate condition of the carapace; though in this connexion it must be remembered that the typical testudinate pattern of five centrals and four laterals was established even among Jurassic amphichelids. The ridley also lacks the specialization of large size shown by other members of the Cheloniidae.

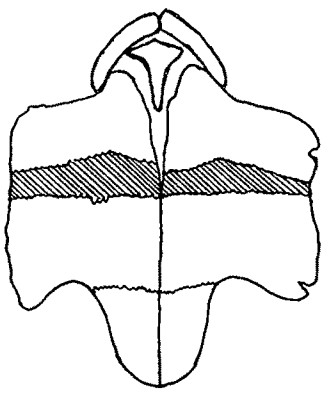

Fig. 1. Plastron of *Lepidochelys olivacea* with mesoplastra

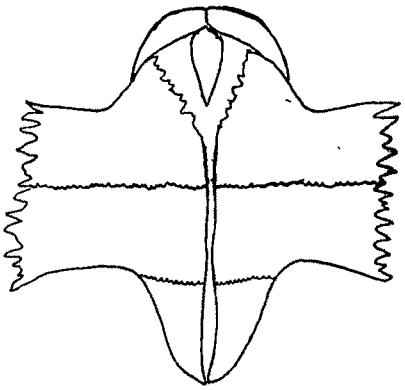

Fig. 2. Normal plastron of *Lepidochelys olivacea*

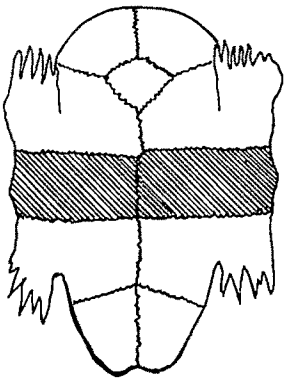

Fig. 3. Plastron of a Jurassic amphichelid (*Pleurosternum* sp.) from the Purbeck Limestone of Swanage, Dorset (Oxford University Museum No 13797)

In view of the symmetry of these aberrant 'mesoplastra', their occurrence in the primitive *Lepidochelys* and the close similarity between them and the mesoplastra of amphichelids, one is tempted to suggest that they have a true homology with the mesoplastra of primitive turtles. However, considering the very long time since a *Lepidochelys* ancestor had mesoplastra, it is perhaps more likely that the present specimen merely shows a casual division of embryonic ossification centres. Neither hypothesis can be tested, of course, even if the specimen were in hand.

I thank Dr. Ernest Williams of Harvard University for his advice.

Collection of the Liquid Fraction of Bee Venom

THE liquid fraction of honey bee venom (*Apis mellifera* L.) can be collected by a modification of the device described by Benton, Morse and Stewart[1] and Benton[2].

This device consists of a flat surface over which steel wires are stretched at $\frac{1}{4}$-in. (6·36-mm) intervals. The wires are alternately grounded and charged. The bees, on being shocked, sting down through a sheet of nylon parchment taffeta; the venom is left on the underside of

the nylon when the sting is removed by the bee. The venom is allowed to dry and is then scraped free with a sharp blade. The venom so collected is slightly contaminated with pollen grains and dust.

To collect the liquid fraction, two sheets of thin polyethylene ('Handiwrap', Dow Chemical Co.) (0·0254-mm thick) are stretched over the collection board and under the nylon parchment taffeta; the sting of the honey bee cannot easily penetrate thicker sheets of polyethylene. The bees, when shocked, sting down through the taffeta and the two sheets of polyethylene. The venom is deposited as small droplets on the underside of the last sheet of plastic. The first sheet of polyethylene, covered with contaminants, is discarded. It is possible to collect about 2 g of venom from twenty colonies of bees in about 2 h with the original apparatus; the modified apparatus described here collects only about half that amount.

Some venom is lost between the sheets of plastic and in the nylon, but the material that is obtained is free of contaminants. To obtain the venom as a liquid, one must remove the last sheet of plastic rapidly, extract it with physiological saline solution or de-ionized water and quick-freeze the solution. Pure, dried venom can be obtained by drying the solution under aseptic conditions.

The thin sheet of polyethylene does not retain the stingers and the bees do not appear to suffer any adverse effects in the process of venom collection.

This investigation was supported by a U.S. Public Health Service predoctoral fellowship and a grant from the National Institutes of Health.

Pregnancy Failure in Laboratory Mice after Multiple Short-term Exposure to Strange Males

An olfactorily induced pregnancy failure in recently inseminated laboratory mice has been shown to result from enforced cohabitation with a strange or alien male, following which the female would return to oestrus[1]. The females were exposed for a period of 12, 24, 48, or 72 h, with maximum pregnancy failure (approximately 80 per cent) occurring at the two longer periods, and about half as many failures with 12 h exposure[2,3]. In the aforementioned experiments, the female was continually subjected to the presence of the strange male. The purpose of the present investigation was to determine if multiple, short-term exposures of the newly inseminated female to strange males would reduce the pregnancy rate.

Our experiments were conducted with virgin albino females, 50–60 days of age, weighing approximately 25 g, and showing a perforate vaginal orifice. Opaque plastic window boxes 22 in. by 5·25 in. by 5·5 in. high with wire mesh tops were used throughout as cages. Females were paired individually with a stud male (albino) of proved fertility and examined each morning for the presence of a vaginal plug. The male was removed from the female's cage when she showed a vaginal plug. The female remained in her home cage for 24 h, after which she was subjected to one of four treatments, as follows: The female was (*a*) left undisturbed in her cage for 7 days (control); (*b*) placed for 7 days in a cage containing a resident wild male house mouse; (*c*) transferred to a cage containing a resident wild male house mouse for three 15 min periods per day for 4 days; (*d*) transferred to an empty cage for periods identical to (*c*). Each treatment consisted of fifty animals. Females were killed on the seventh day in order to determine whether or not they were pregnant. All treatments were tested for significance by χ^2 analysis. Wild males were used as strange males, in part to prove their capacity to block pregnancies and in part to provide as wide a spectrum of odours as possible, thus assuring maximum pregnancy failure.

For the fifty females in treatment *a* there were forty-five pregnancies (90 per cent), while those in treatment *b* had only twenty-two pregnancies (44 per cent). This is a significant reduction in pregnancy rate ($P < 0.001$). For the fifty females subjected to wild males for short periods (treatment *c*) there were twenty-five pregnancies (50 per cent). This pregnancy rate is also a significant reduction from the control ($P < 0.001$) but is not significantly different from the constant exposure to the wild males (treatment *b*). Of the fifty females exposed to empty cages (treatment *d*) there were forty pregnancies (80 per cent), which was a significant increase in pregnancy rate from the continuous or periodic exposure to the wild males ($P < 0.001$) but was not significantly different from the control (treatment *a*).

Our data indicate that multiple short-term exposure of a recently inseminated female to a wild male will cause essentially the same degree of pregnancy failure as the continuous exposure to a wild male. The 15 min exposure may be considered a longer period of contact than might occur under natural conditions; however, we believe that the short exposure approximates more closely the degree of contact in the environment than continuous exposure. Since the exposure periods were 4–12 h apart, we suggest that in the natural habitat the periodic contact of a recently inseminated female with several male mice or trails containing their odours would be adequate to induce some pregnancy failure, and thus would contribute toward decreased recruitment in the population. Recent investigations[4,5] indicate (*a*) in two high-density natural populations, a general failure of adult females to become pregnant as well as an increase in the percentage of parous, non-pregnant females in the older age classes at the time of and immediately following the peak in the population; and (*b*) an increase in the reproductive rate when females from confined populations were allowed to disperse into uninhabited areas.

MICROBIOLOGY

Some Observations on Staphylococcal Pigmentation

Various substances added to nutrient agar media are known to enhance colonial pigmentation of *Staphylococcus aureus*. These include sterile cow's milk[1,2], fermentable carbohydrate[3], sodium chloride[4], glycerophosphoric acid[5] and glycerol monoacetate[6]. Not all these are equally effective, however, the most intense pigmentation being developed on milk agar and on glycerol monoacetate agar. Glycerol monoacetate agar has the additional advantage that strains of *Staph. aureus* growing

on it can be readily differentiated into a number of colour varieties—yellow, orange, buff and white—after incubation for 48 h. In our hands, milk agar has given irregular results. Thus, although the medium has consistently induced strongly pigmented growth, some batches of it have shown little or no differentiation between the colour types, even after prolonged incubation, while other batches have developed striking colour differentiation after incubation for only 24 h. These inconsistencies led us to examine different components of cow's milk in order to determine the nature of its pigment-stimulating fraction.

In an earlier study of the pigment-stimulating properties of milk, Johnston[7] found that neither casein nor lactose appreciably increased pigmentation, but he obtained good pigmentation on media containing calcium. Our investigations with skimmed milk, and with some of the substances present in the water phase of milk, including lactose, calcium, casein and citrate, have yielded disappointing results. A wide range of concentrations of these substances, both singly and in various combinations, was examined in heart infusion agar (Difco), but in no case was colonial pigmentation of staphylococci much stronger than on the nutrient base without these additives. Skimmed milk agar supported moderate orange pigmentation of some strains, but the colour was never very intense and colour differentiation was absent.

Since cream agar[8], which consists of the 'top off the bottle' of unhomogenized cow's milk, added to the nutrient agar base to give a final concentration of 10 per cent, gave consistently intense colonial pigmentation with obvious colour differentiation after incubation for 48 h, we next tested 'pure' cream fat as a pigment-stimulating substance. Cream fat was extracted from ordinary commercial cream either by ether extraction or by heating at 60° C after preliminary separation by centrifugation, and butter-fat was separated from commercial butter by heating at 60° C. These fats, which were emulsified into the hot molten nutrient agar base with a Silverson mixer, gave very intense colonial pigmentation and overt colour differentiation at 48 h.

It was now clear that the fat components of whole milk are the factors responsible for enhanced colonial pigmentation of *Staph. aureus* growing on milk agar, an observation that is in accord with the pigment-stimulating effect of glycerol monoacetate.

The two components of cream and butter-fat—glycerol and fatty acids—were next examined. Although Willis and Turner[6] reported that glycerol does not significantly enhance staphylococcal pigmentation, the alcohol was re-examined, but again with negative results. The fatty acids of cream and butter were obtained (1) by saponification of the fat with alcoholic sodium hydroxide, acid precipitation, and washing, and (2) by digestion of the fat with excess of aqueous pancreatic lipase (Calbiochem), separation by heating to 60° C, and washing. These mixtures of fatty acids were neutralized with 1 N sodium hydroxide, sterilized and incorporated into the nutrient agar base. On these cream- and butter-soap media, staphylococcal pigmentation was more intense than we have seen on any other medium, and excellent colour differentiation was obtained after incubation for only 24 h.

Of the various fatty acids present in cream and butter-fat, we obtained commercial preparations of those listed in Table 1, and tested them at a range of concentrations in the nutrient agar base. The results shown in Table 1 are those obtained after incubation for 48 h, at the optimum concentration for each of the fatty acids tested.

Human fat[6] incorporated into the nutrient base by emulsification causes colonial pigmentation and colour differentiation which is at least as good as that obtained with cream and butter fat, but cod liver oil is not quite so effective.

These observations, which will be reported in detail elsewhere, indicate that staphylococcal pigmentation is greatly favoured by the presence of a variety of fatty acids. Mevalonate, which is an intermediate in the carotenoid pathway, itself enhances pigmentation slightly, but is much less active than the fatty acids. Carbohydrate metabolism appears to contribute very little towards colonial pigmentation.

Effect of Bacitracin on *in vitro* Phagocytosis

PREVIOUS investigations of the influence of antimicrobial compounds on phagocytosis indicated that polypeptide antibiotics like bacitracin and polymyxin *B* retarded ingestion of polystyrene latex (PSL) particles or *Staphylococcus aureus* by guinea-pig polymorphonuclear leucocytes (PMN)[1]. Although the levels of antibiotic necessary to produce this inhibition exceeded the therapeutic level for the guinea-pig, it was of interest to discern the mode of action of this peptide on the ingestion process and possibly gain further insight as to the basic mechanism of phagocytosis. This communication embodies some of the evidence for the chelating effect of the peptide and the essential participation of metal ions in phagocytosis.

The acquisition and preparation of PMN together with the determination of phagocytic activity in the presence of bacitracin were performed as previously described[1]. The washed polymorphonuclear leucocytes were allowed to ingest particles in Krebs–Ringer solution with and without $MgSO_4 \cdot 7H_2O$ and calcium chloride. All media were prepared with de-ionized, glass distilled water. Baci-

tracin was added as indicated. The phagocytic index was expressed as:

$$P.I. = \frac{\text{Number of PMN with} > 10 \text{ particles/cell}}{500 \text{ PMN counted}}$$

Phagocytosis of PSL and *Staph. aureus* by PMN was significantly reduced in the absence of Mg^{++} and Ca^{++} (Fig. 1). The addition of bacitracin or EDTA to a medium containing these ions likewise decreased the number of particles ingested. It can be seen in Fig. 1 that phagocytosis was almost fully restored if Mg^{++} or Ca^{++} was provided after a 30-min period of incubation in a medium which was initially devoid of these ions. It was also noted that the chelator EDTA exerted appreciably less effect on ingestion of PSL than staphylococci.

While serum, used at a concentration of 30 per cent, exerted little effect on the ingestion of PSL by PMN, it stimulated the engulfment of staphylococci by 20 per cent or more. The inhibition by bacitracin or EDTA was observed in the absence of serum. Since PSL and bacteria exhibited different properties relative to their adsorption in the presence of serum, it was omitted from experiments which tested the reversal of bacitracin inhibition by metal ions.

An indication of the chelating effect of bacitracin became evident when phagocytic ingestion was observed to decrease in Krebs buffer solution; a medium which contains metal ion levels very near those in serum. When phagocytosis was conducted in Krebs medium, the *P.I.* decreased in proportion to the concentration of bacitracin. Maximal retardation of ingestion occurred when the concentration of bacitracin was approximately 1·4 mM (Fig. 2) assuming a molecular weight of 1,422 (ref. 2).

The addition of Mg^{++} or Ca^{++} reversed the inhibition by bacitracin, the latter being more effective up to the concentration found in serum. Further increase in Ca^{++} resulted in an appreciable decrease in phagocytosis of PSL while increasing Mg^{++} appeared to potentiate the ingestion (Fig. 2). The bottom abscissa in the figure represents values obtained in the presence of 1·4 mM bacitracin. The antibiotic appeared to bind or promote the binding of several moles of Mg^{++} per mole of peptide since at the point of complete restoration of ingestive capability the ratio of Mg^{++} to bacitracin was 14 : 1.

The notion that bacitracin prevents phagocytosis by competition for metal ions and thus thwarts adsorption is suggested in the following experiment: A suspension of PMN in Krebs buffer was permitted to adsorb PSL at 0° C in the absence of bacitracin for 15 min. The excess (non-adsorbed) PSL was then washed off and the polymorphonuclear leucocytes were examined microscopically to assess the adsorption. Afterwards, bacitracin was added and the polymorphonuclear leucocytes were incubated for 30 min at 37° C. A significant degree of ingestion was observed (Table 1). If the polymorphonuclear leucocytes were allowed to incubate for 15 min at 0° C in the presence of bacitracin prior to the 'confrontation' with PSL, the usual retardation of ingestion occurred.

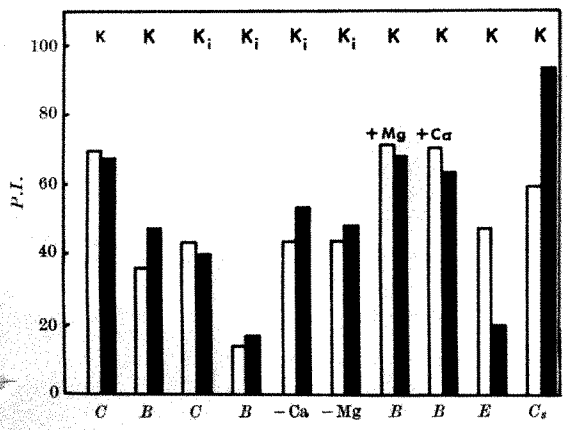

Fig. 1. Phagocytosis of PSL and *Staphylococcus aureus* with and without added metal ions. Each test mixture contained particles and PMN as in Table 1; Krebs buffer (*K*) or Krebs buffer minus Ca^{++} and Mg^{++} (K_i), 67 mM, *p*H 7·4; and $MgSO_4 \cdot 7H_2O$, 15 mM; calcium chloride, 3·0 mM; EDTA, 5·0 mM (*E*) and bacitracin, 1·4 mM (*B*) where indicated. *C*, Control with no bacitracin; C_s, serum added to 30 per cent

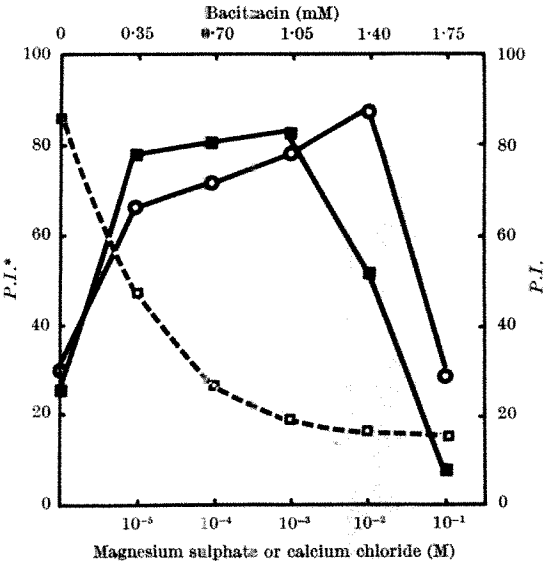

Fig. 2. The reversal of bacitracin inhibition by metal ion. The phagocytic index (*P.I.**) on the left ordinate is expressed as a percentage of the control value, that is the phagocytosis which occurred without bacitracin in complete medium was taken as 100 per cent. The values are a function of those on the bottom abscissa. The *P.I.* on the right ordinate is expressed as in the text and the values are a function of those on the top abscissa. —■—■—, magnesium sulphate; —○—○—, calcium chloride; – – □ – – □ – –, bacitracin

Table 1. ADSORPTION OF PSL PRIOR TO, DURING AND AFTER TREATMENT OF PMN WITH BACITRACIN

Phagocytic system		*P.I.*	*P*
(1) PMN + PSL	37° C, 30 min	67·80 ± 10·70	—
(2) PMN + PSL + BAC	37° C, 30 min	28·15 ± 3·20	< 0·001
(3) PMN + PSL	(0°C, 15 min)		
+ BAC	37° C, 30 min	38·10 ± 3·84	< 0·001
(4) PMN + PSL	0° C, 15 min	8·60 ± 2·12	< 0·001
(5) PMN + PSL	(0°C, 15 min)		
	37° C, 30 min	61·70 ± 3·26	> 0·100
(6) PMN + PSL + BAC	0° C, 15 min	0·10 ± 0·14	< 0·001

Each phagocytic system contained: Krebs buffer, *p*H 7·4, 67 mM; PMN, $2·0 \times 10^7$; PSL, $5·0 \times 10^8$; bacitracin, 1·4 mM where indicated and saline, 0·87 per cent to a final volume of 2·0 ml. The pre-incubation period for adsorption of PSL at 0° C is indicated in parentheses. The *P.I.* and standard error are given in each case. *P* has the usual connotation of significance and refers to the difference between cells ingesting particles after adsorption in the absence and presence of bacitracin. PMN, Polymorphonuclear leucocytes; PSL, polystyrene latex; BAC, bacitracin.

It thus appears that phagocytes which have successfully adsorbed particles are committed to ingest them. The failure of bacitracin to retard ingestion after adsorption suggests that its mode of action is primarily on adsorption and not ingestion. The innocuous effect of the peptide on certain metabolic reactions of PMN (ref. 1) would lend further support to this concept.

Some adsorption or ingestion was noted in the absence of Mg^{++} and Ca^{++} with added bacitracin. The phagocytic system may not be totally deplete with respect to Mg^{++} and Ca^{++} since the PMN could easily have retained tightly bound Mg^{++} or Ca^{++} throughout the preparative procedure. In short, phagocytosis in a given population of PMN cannot be completely terminated unless an actual repulsive barrier is established. Experiments which make it possible to assess properly the interplay of repulsive and attractive forces which occur on the surface of the PMN during phagocytosis constitute a formidable problem in cell biology. Also, while a bridge involving Ca^{++} may be prevalent in one case, the preference for Mg^{++} may be

manifest in another. Such might be the reason for the difference in restorative character of Mg^{++} and Ca^{++} as presented here.

The notion that phagocytosis can be explained in terms of the simple colloidal stability theory of Verwey and Overbeck[3] has been discounted[4] because of a lack of correlation in the zeta-potential of either cells or test particles. A mechanism of phagocytosis involving cross-linking of serum proteins between cells and particles has been proposed[5]. The role of Ca^{++} in adsorption of protein on to the cell surface has been suggested in investigations on the flocculation of bacteria by colloids[6]. In a similar way serum components which bind Ca^{++} very strongly at or near their isoelectric point have been postulated[7].

In view of the evidence presented here, the divalent metal ion although not indispensable in phagocytosis seems to play a supportive part in it. Since Ca^{++} can bind peptides and thereby impart a net positive charge, its association with the negatively charged cell might promote the 'physiological adsorption' which is essential to 'physiological ingestion'. At physiological *p*H bacitracin should, to a certain extent, bind Ca^{++} (refs. 2, 8). The link resulting from this union may then be peptide to peptide or cell to peptide. The competition for a binding site on the cell surface might be such that particles, even if protein coated, would not be adsorbed in a manner sufficient to initiate ingestion. The chemical nature of the surfaces involved must be elucidated before the initial phases of the mechanism of phagocytosis can be understood.

VIROLOGY

Isolation of Parainfluenza-3 Virus from Water Buffaloes in Egypt

ALTHOUGH various workers have reported the isolation of myxovirus parainfluenza-3 from cattle from different parts of the world[1–4], there is no report of similar viruses from water buffaloes. This report describes briefly the isolation of myxovirus parainfluenza-3 from buffalo calves suffering from pneumoenteritis.

The two strains *MP*-3(45) and *MP*-3(83) were isolated in primary calf kidney cell cultures from the nasal and faecal swabs respectively taken from buffalo calves showing clinical signs of pneumoenteritis. On primary isolation in calf kidney cultures, grown in medium consisting of 0·5 per cent lactalbumin hydrolysate in Hanks's balanced salt solution, cytopathic effect was first observed after 5 days as focal rounding of refractile cells. This progressed to form large and small syncytia. The cell sheet came off the glass wall of the tissue culture tubes after 10–12 days' incubation. On subsequent passages in calf kidney cells, cytopathic effect appeared within 36 h. Both strains formed well-defined plaques on buffalo and calf kidney monolayers. On the seventh day after inoculation, plaques measured 1–1·5 mm on calf kidney cells

Fig. 1. After 7 days of incubation plaques resulting from the inoculation of 10^{-5} (bottle No. 1) and 10^{-6} (bottle No. 2) dilutions of *MP*-3 (45) virus

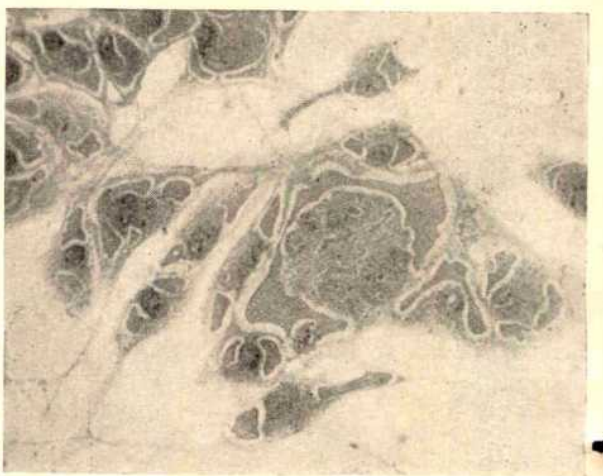

Fig. 2. Cytoplasmic and intranuclear inclusion in water buffalo kidney cells 8 days after inoculation with buffalo strain *MP*-3 (45) of parainfluenza-3 virus. Zenker's haematoxylin and eosin. (× *c.* 334)

(Fig. 1). The titre of the infected fluid was generally $10^{7.8}$ P.F.U. per ml.

These agents produced cytopathic effect in calf, buffalo calf and goat kidney cultures. The viruses also produced distinct intranuclear and intracytoplasmic eosinophilic inclusions in calf, buffalo and camel kidney cultures. Fig. 2 shows inclusions produced by *MP*-3(45) in buffalo kidney cells. Isolate *MP*-3(45) produced giant cells and cytoplasmic inclusions in *MS* cell cultures, and a few cells showed intranuclear inclusions. At 4° C virus *MP*-3(83) agglutinated buffalo, cattle and sheep erythrocytes at high titres (1 in 128) and agglutinated chicken

Table 1. SEROLOGICAL RELATIONSHIP AMONG BOVINE PARAINFLUENZA-3 VIRUS AND BUFFALO STRAINS OF *MP*-3 VIRUS

Virus	Titre of sera* versus indicated virus					
	MP-3 (45)		*MP*-3 (83)		*MP*-3 (Ohio)	
	Neut†	HI‡	Neut†	HI‡	Neut†	HI‡
MP-3 (45)	10,000	8,000	5,000	10,000	5,000	2,000
MP-3 (83)	10,000	2,000	5,000	10,000	2,000	500
MP-3 (*S*) (cattle strain)	5,000	2,000	5,000	5,000	1,000	2,000

* Sera were prepared in rabbits except *MP*-3 (Ohio) which was prepared in calf with no antibodies before infection.
† 100–200 PFU of virus were used in neutralization test.
‡ Against four haemagglutinating units of each virus.

and guinea-pig red cells at low titres (1 in 4), whereas *MP*-45 strain agglutinated sheep, cattle and buffalo red cells at high titre (1 in 128) but did not give haemagglutination with chicken and guinea-pig erythrocytes. This indicates the biological difference between these two strains and also between them and the cattle strains of *MP*-3 virus being studied in our laboratory[5]. Both viruses gave haemadsorption with sheep, cattle and guinea-pig erythrocytes. Exposure of both types to 40 per cent diethyl ether for 30 min at 37° C resulted in complete loss of infectivity as determined by the plaque technique. These agents are also sensitive to 1 per cent trypsin (Difco 1 in 250) and 1 : 500 dilution of sodium deoxycholate. The viruses were neutralized by bovine parainfluenza-3 immune sera kindly supplied by Drs. Hamdy and Bohl of Ohio Agricultural Experimental Station, Wooster, Ohio. As shown in Table 1, cattle and buffalo strains appear to be serologically identical. These viruses seem to possess a unique biological quality regarding their haemagglutination spectrum. Studies are in progress to determine the etiological role of these viruses for the little-studied respiratory diseases of water buffaloes, which are important domestic animals in the Eastern countries.

PSYCHOLOGY

Spontaneous Alternation and Exploration in Rats

WHEN tested in a T-maze rats tend to alternate their choices spontaneously[1]; that is, when given two successive trials they tend to choose first one arm then the other, rather than the same arm on both trials. They alternate even when no choice has been made on the first trial; thus, if put directly into the goal box at the end of one arm of a previously explored T-maze, and then given a choice between the two maze arms, they will tend to choose the arm leading to the other goal box[2]. In general there is a tendency to go to the part of the environment that has been least recently explored.

A possibly related phenomenon has been found in a T-maze in which one arm leads to a Dashiell maze (a symmetrical network of alleys intersecting at right angles —it will be referred to as a D-maze), while the other ends in a blind alley[3,4]. After a few trials rats show an increasing tendency to choose the arm leading to the D-maze. Like alternation, this may be due to a tendency to go to the part of the environment that has been least recently explored. For if a rat has two areas to explore (such as the D-maze and blind alley), and is given the same time in each, there will tend to be more unexplored, or less recently explored, parts of the larger area; it should therefore choose the path leading to this area more frequently than that leading to the smaller area. Thus rats will prefer the arm leading to the D-maze.

This D-maze experiment has been interpreted rather differently by Berlyne and Slater[5]. They suggest that rats prefer the D-maze because of an aversion for a maze arm in which movement is relatively restricted, as in a blind alley. In support of this interpretation they report an experiment in which rats fail to show any preference for an arm leading to a goal box containing novel stimuli, when the other arm leads to an equally spacious goal box containing familiar stimuli. This implies that the opportunity to explore novel stimuli is not rewarding to rats, and therefore it cannot be the opportunity to explore the D-maze that gives rise to the preference for the arm leading to it. However, while in alternation and the D-maze experiments the environment is more or less stable, in Berlyne and Slater's experiment part of the environment must change from trial to trial; this might produce fear, which would complicate the interpretation of the results. In the following experiment, the tendency to go to the part of the environment that has been least recently explored is pitted against the supposed tendency to avoid places where movement is restricted, using a maze in which the environment is stable.

Twelve male hooded rats were used. The floor plan of the apparatus, consisting of an alley maze of unpainted aluminium, is shown in Fig. 1. On every trial a rat was put into the stem, *S*, and when it had entered one of the arms *A*, *B*, *C* or *D*, a door was closed behind it, either restricting it to a single arm (so that the rat was confined in one of the arms *A*, *B*, *C* or *D*) or restricting it to two arms (so that it was confined either to the alley made up of *A* and *B*, or to *C* and *D*). On one side of the maze a rat was always restricted to a single arm (this side will be referred to as *RS*), while on the other side (*URS*) it was always restricted to two arms. For half the rats *RS* was on the left, for half it was on the right. The rats were hungry (being given food for 1·5 h each day, starting 15 min after the day's testing) and were rewarded in the maze as follows: all rats were rewarded with one 45 mg sugar pellet at the end of each of the two *URS* arms; half the rats were rewarded with one pellet in the *RS* arm chosen, half were rewarded with two pellets in this arm. All rats were left in the two *URS* arms for 30 sec before being picked out for the next trial; half were left in the *RS* arm chosen for 30 sec, half were left in this arm for 15 sec. These different conditions were introduced in order to control against preferences due to differences in reward conditions on the two sides of the maze, or to differences in the time left in the maze. Three trials were given per day for 12 days, with 25 sec between trials.

If rats tend to choose the least recently explored part of the environment, even if it is more restricting, they should prefer *RS*, since they will need to choose *RS* twice in order to explore the whole of it, while they will only need to choose *URS* once. The mean number of choices to *RS* was 21·33 (out of a maximum of 36). This is significantly above chance by Wilcoxon's *T*-test ($T = 4$, one-tailed $P < 0{\cdot}005$). None of the differences between subgroups formed either on the basis of amount of reward on *RS*, or time spent on *RS*, were significant by the Mann–Whitney *U*-test. The result thus confirms the prediction from the hypothesis that rats prefer an arm leading to a D-maze to a blind alley because of a tendency to go to the

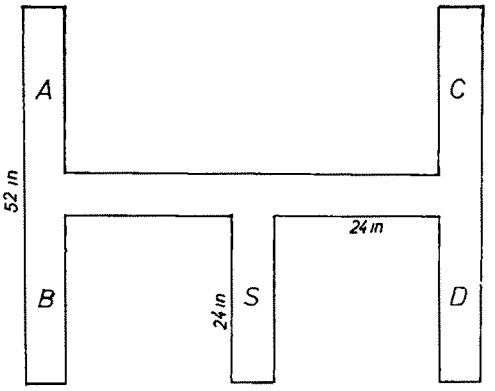

Fig. 1. Ground plan of the maze

least recently explored part of the environment, rather than a tendency to avoid a place where movements are restricted.

In the D-maze experiments, after the rats had settled down to a steady preference, the maze was changed, so that the arm previously leading to the D-maze became a blind alley, and the previous blind alley led to a D-maze. The rats' preferences followed this change, so that they continued to prefer the D-maze. A similar result would be expected in the present experiment if *RS* and *URS* were interchanged. To test this the experiment was continued for a further 12 days, with *RS* and *URS* on the sides of the maze opposite to where they had been for the first 12 days. Contrary to expectation, the preferences did not switch to the new *RS*; the mean number of choices to *RS* was 16·33.

Thus rats prefer an arm leading to a D-maze, and change their preferences when the position of the D-maze is changed; while in the present experiment rats prefer *RS*, part of which is likely to be less recently explored than the rest of the environment, but do not change their preferences when the position of *RS* is changed. The first part of the experiment supports the hypothesis that rats prefer a D-maze because of a tendency, as in alternation, to go to the least recently explored part of the environment. A possible explanation of the failure to change preferences is that when responses are rewarded they become increasingly stereotyped, and rats become insensitive to changes in the environment that do not affect the reward. Thus the preference for *RS* may become fixated and continue even though no longer appropriate to the exploratory tendencies through which it was originally acquired. In the D-maze experiments no primary reward, such as food, was given, so that the preference would not become fixated.

I thank the Medical Research Council for financial support for this research, Mr. A. J. Watson for much helpful discussion and advice and Prof. O. L. Zangwill for continued encouragement.

An Acoustic Factor in Letter Cancellation

CONRAD[1,2] has shown that intrusive errors in the recall of letters presented either auditorily or visually are acoustically similar to the presented items. Thus confusions in recall occurred mainly between *B*, *C*, *P*, *T* and *V* and between *F*, *M*, *N*, *S* and *X*. Subsequent work (for example, Wickelgren[3]) has confirmed and extended these findings.

The following experiment is reported because the results would appear to extend the already important phenomenon of 'acoustic confusion' to an area hitherto considered unrelated to short-term memory.

Twenty naval ratings were presented with foolscap sheets containing a passage of prose reproduced from an article in *Punch*. They were requested to go through the sheets crossing out all the letters '*e*' and were allowed 15 min to complete as much of the material as they could. The emphasis of the instruction lay towards speed rather than accuracy.

The first two paragraphs (329 words) of the completed work were examined to determine which particular *e*'s had remained uncancelled. The results were analysed under three categories: (1) words in which the *e* was pronounced; (2) words in which the *e* was silent; (3) 'the's. The results of this gross analysis are presented in Table 1, from which it is clear that the probability of missing a silent *e* is greater than that for missing a pronounced *e*. This difference is statistically significant ($P < 0.002$, on a two-tailed binomial test). The *e* in 'the' had the greatest probability of being omitted; this being significantly greater than silent *e*'s ($P < 0.024$) and the pronounced *e*'s ($P < 0.002$).

Silent *e*'s are commonly found at the end of words and it was therefore necessary to discover whether it was the predominantly late position of the silent *e* which caused it to be missed rather than the fact that it was silent. Accordingly, a positional analysis was carried out in which the words containing *e*'s were divided into: (1) those in which *e* occurred at the terminal position; (ii) those with *e* in the penultimate position; (iii) those in which *e* occurred in a position other than last or penultimate (the 'early' *e*). Table 2 presents the probabilities of missing an *e* which is silent or pronounced under the three positional categories. It is evident that, after controlling for the position of the *e* in the word, silent *e*'s are still significantly more likely to be omitted than pronounced *e*'s. Position in the word does have an effect, however, in that early *e*'s are less likely to be missed than later ones.

Table 1. PROBABILITIES OF MISSING AN *e* IN 'THE', WHEN PRONOUNCED AND WHEN SILENT

'The'	Pronounced	Silent
0·32	0 04	0·15

Table 2. PROBABILITIES OF MISSING A PRONOUNCED OR SILENT *e* RELATED TO POSITION IN WORD

Position category	Pronunciation category: Pronounced	Pronunciation category: Silent	Significant level (*P*) (pronunciation)
Early in word	0·03	0 06	N.S.
Penultimate	0 07	0·14	0·024
Terminal	0·12	0·18	0·042
	$P = 0.027$	$P = 0.042$	
	N.S.	N.S.	
	Significance level (Position)		

N.S., not significant.

The tentative conclusion to be drawn from these findings is that the acoustic image of a word is scanned as well as the visual stimulus. The results would seem to suggest that the acoustic image is examined for characteristics normally associated with the presence of an *e* in the printed word and that the *e* is more likely to be missed if an acoustic correlate is lacking.

The high proportion of missed *e*'s in 'the' could possibly be due to three factors: (*a*) because the *e* in 'the' is normally pronounced /ə/; (*b*) because the *e* is in the terminal position; (*c*) because 'the' is a highly redundant word. which may be 'taken for granted' and thus not scanned. The first possible explanation (*a*) is probably inadmissible. A comparison was made between words in which the *e* was pronounced /ə/ as in were or inserted with those in which it was pronounced /ɛ/ (as in 'set') or /i/ (as in 'seat') and it was found that /ɛ/ or /i/ were, if anything, the more likely to be missed, but this difference was quite insignificant. (The words used in this comparison were selected such that chance positional factors were controlled.) The second possible explanation (*b*) may be partly true, but cannot be the only explanation, since the *e* in 'the' is much more likely to be missed than terminal *e*'s in other words (see Table 2). The third explanation (*c*) would therefore seem preferable, but further work is needed to establish the case positively.

It is of interest that, since the *e*'s pronounced /ə/ were certainly no more likely to be missed than *e*'s pronounced /ɛ/ or /i/, the nature of the acoustic correlate seemed to be unimportant.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Monday, May 9

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 5 p.m.—Prof. L. Berry "The Nile in the Sudan".

UNIVERSITY OF LONDON (at the Wright-Fleming Institute of Microbiology, St. Mary's Hospital Medical School, London, W.2), at 5 p.m.—Dr. R. C. Valentine: "The Construction of a Virus" (second of a series of four Almroth Wright Lectures).*

BRITISH SOCIETY FOR THE HISTORY OF SCIENCE (in the Council Room of the Science Museum, Exhibition Road, London, S.W.7), at 5.30 p.m.—Dr. A. I. Sabra. "The Representation of White Light—Hooke *v.* Newton".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion on "An Engineer's Ideas on Some of the Electromagnetic Fundamentals" opened by Mr G. F. Shotter.

SOCIETY FOR VISITING SCIENTISTS (at the English Speaking Union, Dartmouth House, 37 Charles Street, London, W.1), at 7.30 p.m.—Discussion Meeting on "Teaching Methods in Biology and Medicine". Chairman: Dr. J. R. Ellis. Speakers. Prof. Marc Klein: "The Training of the Doctor in France"; Dr J. Badenoch "The Tutorial System at Oxford".

Tuesday, May 10

SOCIETY OF CHEMICAL INDUSTRY, AGRICULTURE GROUP (at 14 Belgrave Square, London, S.W.1), at 10.30 a.m.—Annual General Meeting, followed by a meeting on "Tropical Crops".

INSTITUTE OF PETROLEUM (at 61 New Cavendish Street, London, W.1), at 2 p.m.—Annual General Meeting. 5.30 p.m.—Mr. A. Schilling: "A New Step in the Appreciation of Lubricants for Modern Automotive Diesel Engines"

UNIVERSITY OF LONDON (at the Middlesex Hospital Medical School London, W.1), at 5 p.m.—Prof Lord Cohen of Birkenhead: "Why Study Medical History?"*

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5 p.m.—Scientific Papers.

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Dr. S. Jones: "Automatic Control in Railway Systems".

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Mr. G. P. Hutchinson. "Interlocking in Large Electricity Substations—a Fundamental New Approach".

PARLIAMENTARY AND SCIENTIFIC COMMITTEE, GENERAL COMMITTEE (in Committee Room 6, House of Commons, Westminster, London, S.W.1), at 5.30 p.m.—Discussion on "Recent Developments with Regard to Antibiotics and the Control of Infections", initiated by Dr. Frank Hartley and Dr F. L. Rose.

UNIVERSITY OF LONDON (at Imperial College of Science and Technology, Royal School of Mines, London, S.W.7), at 5.30 p.m.—Prof D. W. Fuerstenau: "Mineral-Water Interfaces III. An Interfacial Approach to the Geochemistry and Extraction Metallurgy of Sea Floor Nodules".*

UNIVERSITY OF LONDON (at the Institute of Archaeology, 31–34 Gordon Square, London, W.C.1), at 5.45 p.m.—Mr. D. H. French: "Excavations at Can Hasan, 1961–65".*

SOCIETY OF CHEMICAL INDUSTRY, PLASTICS AND POLYMER GROUP (in the Film Theatre, Shell Mex House, Strand, London, W.C.2), at 6 p.m.—34th Annual General Meeting.

Wednesday, May 11

GEOLOGICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. R. W. R. Rutland: "A Tectonic Study of Part of the Philippine Fault-Zone", Dr W. W. Bishop and Dr. A. F. Trendall: "Erosion-Surfaces, Tectonics and Volcanic Activity in Uganda".

ZOOLOGICAL SOCIETY OF LONDON (at the Zoological Gardens, Regent's Park, London, N.W.1), at 5.30 p.m.—Annual General Meeting, followed by Mr. R. S. R. Fitter: "A Year's Work for Conservation".

CHALLENGER SOCIETY (at the Linnean Society, Burlington House, Piccadilly, London, W.1), at 5.45 p.m.—Annual General Meeting, followed by Mr. L. Draper: "The Benefits of Wave Research".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS DIVISION (at Savoy Place, London, W.C.2), at 6 p.m.—Prof D. Gabor, F.R.S. "Holography".

Thursday, May 12

MINERALOGICAL SOCIETY (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 3 p.m.—Meeting on "The Nature and Origin of Ore-forming Fluids".

UNIVERSITY OF LONDON (at Bedford College, Regent's Park, London, N.W.1), at 5.15 p.m.—Prof N. Miliott. "Evolution and the Eye of the Beholder—Victorian Biological Science in Retrospect".*

UNIVERSITY OF LONDON (in the Beveridge Hall, Senate House, London, W.C.1), at 5.15 p.m.—Prof. B. M. Foss. "Education as Art, Science and Technology—a Psychologist's View" (inaugural lecture).*

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Informal Discussion on "Prevention of Air Entrainment in Vortices", introduced by Mr. G. A. J. Young.

UNIVERSITY OF LONDON (at the Middlesex Hospital Medical School, London, W.1), at 5.30 p.m.—Prof. Fred Lembeck (Tubingen). "Successful Errors in Pharmacology".*

Friday, May 13

INSTITUTION OF ELECTRICAL ENGINEERS, CONTROL AND AUTOMATION DIVISION (at Savoy Place, London, W.C.2), at 5.30 p.m.—Discussion Meeting on "The C.E.I.—Its Implications on Engineering Courses", opened by Prof M. G. Say.

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 9 p.m.—Prof Ronald King: "Your Servant—The Electron".

Saturday, May 14

ASSOCIATION OF CLINICAL BIOCHEMISTS, SOUTHERN REGION (at the Middlesex Hospital Medical School, Cleveland Street, London, W.1), at 10.15 a.m.—Meeting on "Some Aspects of Enzymology".

Monday, May 16

INSTITUTION OF ELECTRICAL ENGINEERS, POWER DIVISION (at Savoy Place, London, W.C.2)—Colloquium on "Main Power Distribution in Industry".

UNIVERSITY OF LONDON (at the Wright-Fleming Institute of Microbiology, St. Mary's Hospital Medical School, London, W.2), at 5 p.m.—Prof M. Abercrombie: "The Pathology of Cell Movement" (third of a series of four Almroth Wright Lectures).*

UNIVERSITY OF LONDON (in the Botany Theatre, University College, Gower Street, London, W.C.1), at 5 p.m.—Prof. David H. Brown (Washington University, St. Louis): "Enzymic Reactions in Glycogen Synthesis".*

UNIVERSITY OF LONDON (at Bedford College, Regent's Park, London, N.W.1), at 5.30 p.m.—Prof. A. Tarski: "What are Logical Notions?"*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER and an ASSISTANT LECTURER (with a special interest in either pure mathematics or statistics) IN MATHEMATICS—The Registrar, University of Strathclyde, George Street, Glasgow, C.1 (May 12).

LECTURER (with qualifications in educational psychology and/or sociology) IN EDUCATION—The Registrar, Bradford Institute of Technology, Bradford, quoting Ref. 131Y/E (May 12)

ASSISTANT LECTURER or LECTURER (preferably with experience in some branch of phycology) IN THE DEPARTMENT OF BOTANY—The Registrar, The University, Liverpool, 3, quoting Ref. CV/32 (May 14).

DIRECTOR OF THE AUDIO-VISUAL AIDS AND PROGRAMMED LEARNING UNIT—The Registrar, The University, Liverpool, quoting Ref. CV/11/N (May 14).

LECTURERS/ASSISTANT LECTURERS (4) (with a good honours degree, appropriate research or teaching experience, and preferably with an interest in one or more of the following fields Vertebrate zoology, embryology, physiology, histology or marine ecology) IN THE ZOOLOGY SECTION OF THE DEPARTMENT OF BIOLOGICAL SCIENCES—The Registrar, Portsmouth College of Technology, Hampshire Terrace, Portsmouth, Hampshire (May 14).

ASSISTANT EXPERIMENTAL OFFICER (with a pass degree, H.N.C., F.I.M.L.T. or similar qualification, previous laboratory experience, and preferably a working knowledge of microbiology) for work concerned with genetical aspects of animal diseases and to supervise the running of a mouse colony—The Secretary, A.R.C. Animal Breeding Research Organization, King's Buildings, West Mains Road, Edinburgh, 9 (May 16).

LECTURER (with a good honours degree in engineering and preferably an interest and experience in thermodynamics) IN MECHANICAL ENGINEERING—The Registrar, The University, Newcastle upon Tyne, 2 (May 16).

LECTURER (with a good honours degree in physics, academic or industrial research experience, and preferably with research interests in one of the following fields: acoustics, nuclear physics; magnetism or biophysics) IN THE DEPARTMENT OF PURE AND APPLIED PHYSICS—The Secretary, Royal College of Advanced Technology, Salford, 5 (May 16).

MAP CURATOR (preferably geography graduate with an interest in maps and bibliographic work) IN THE DEPARTMENT OF GEOGRAPHY—The Registrar, The University, Leeds, 2 (May 16).

LECTURER IN HUMAN PHARMACOLOGY IN THE DEPARTMENTS OF THERAPEUTICS AND PHARMACOLOGY—The Secretary, University of Edinburgh, South Bridge, Edinburgh (May 18).

LECTURER or SENIOR LECTURER IN HISTOLOGY OR NEUROANATOMY IN THE DEPARTMENT OF ANATOMY, Faculty of Medicine—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (May 19).

ASSISTANT IN PSYCHOLOGY for work in social psychology—The Secretary to the University Court, The University, Glasgow (May 20).

ASSISTANT LECTURER or LECTURER (with research experience in the fields of structural and metamorphic geology) IN THE DEPARTMENT OF GEOLOGY—The Secretary, University College, Gower Street, London, W.C.1 (May 20).

ASSISTANT LECTURER (preferably with an interest in quantitative genetics or population biology) IN THE DEPARTMENT OF AGRICULTURAL BOTANY—The Registrar, University College of North Wales, Bangor, North Wales (May 20).

ASSISTANT LECTURER (preferably with research experience in fields other than soils or dairying) IN THE SECTION OF FOOD AND AGRICULTURAL BACTERIOLOGY (situated in the Department of Agriculture)—The Registrar, The University, Leeds, 2 (May 20).

EXPERIMENTAL OFFICER (with H.N.C. or equivalent qualifications and preferably experience in gas chromatography and scintillation counting) IN PHARMACEUTICAL CHEMISTRY to work under the Professor of Pharmaceutical Chemistry—The Registrar, Bradford Institute of Technology, Bradford (May 20).

I.B.M. FELLOW (with a good honours degree or Ph.D in some branch of science or engineering and at least one year's experience in programming a digital computer) IN SIMULATION STUDIES IN THE DEPARTMENT OF SYSTEMS ENGINEERING—The Secretary, University of Lancaster, Bailrigg House, Lancaster (May 20).

ASSISTANT LECTURER IN PHILOSOPHY—The Registrar, Magee University College, Londonderry, Northern Ireland (May 21).

LECTURER IN EDUCATION in the field of the psychology of education—The Registrar, The University, Nottingham (May 21).

DEMONSTRATOR/SENIOR DEMONSTRATOR IN THE DEPARTMENT OF ZOOLOGY—The Registrar, The University, Newcastle upon Tyne, 2 (May 23).

TEMPORARY LECTURER or ASSISTANT LECTURER IN GEOCHEMISTRY IN THE DEPARTMENT OF EARTH SCIENCES—The Registrar, The University, Leeds, 2 (May 23).

LECTURER (graduate in biochemistry with postgraduate qualifications) IN THE DEPARTMENT OF BIOCHEMISTRY, University of Ibadan, Nigeria—The Secretary, Senate Committee on Higher Education Overseas, University of London, Senate House, London, W.C.1 (May 24)

COMPUTING ASSISTANT (with a good honours degree in mathematics or in a pure or applied science, together with some experience of large-scale digital

computing machines) IN THE ELECTRONIC COMPUTING LABORATORY—The Registrar, The University, Leeds, 2 (May 27).

LECTURERS (preferably with experience in theoretical physics, experimental nuclear physics, solid state physics or astrophysics) IN PHYSICS—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (May 27).

LECTURER IN THE DEPARTMENT OF MEDICAL PHYSICS to take charge of and pursue research in clinical physics work embracing radioisotopes and scanning, radiotherapy and radiodiagnosis—The Secretary, The University, Aberdeen (May 28).

SENIOR LECTURER or LECTURER IN THE DEPARTMENT OF PHYSICS—The Registrar, The University, Keele, Staffs (May 28).

ASSISTANT LECTURER (Probationary) or LECTURER (man or woman graduate, with special interests in stratigraphy, including palaeontology and/or sedimentary geology) IN GEOLOGY—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (May 30).

LECTURER/SENIOR LECTURER and a LECTURER IN THE DEPARTMENT OF MATHEMATICAL STATISTICS, University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, May 30).

LECTURERS/SENIOR LECTURERS (2) IN THE DEPARTMENT OF PHYSIOLOGY, University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, May 30).

ASSISTANT LECTURER (with special qualifications in some field of experimental botany) IN THE DEPARTMENT OF BIOLOGY—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8 (May 31).

LECTURERS IN THE DEPARTMENT OF ELECTRICAL ENGINEERING—The Registrar, The University, Newcastle upon Tyne, 2 (May 31).

SENIOR LECTURER/LECTURER IN GEOGRAPHY at the University of New England, Armidale, New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, May 31).

SENIOR LECTURER or LECTURER (with a Ph.D. degree or equivalent) IN PHYSICAL CHEMISTRY at the University College of Townsville, University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (London and Brisbane, June 3).

PROFESSOR OF PURE MATHEMATICS at the University of New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, June 30).

READER/SENIOR LECTURER/LECTURER IN THE DEPARTMENT OF HISTORY AND PHILOSOPHY OF SCIENCE, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, June 30).

LECTURER or SENIOR LECTURER (with a degree in veterinary science registrable in the State of Victoria, preferably with postgraduate experience in teaching and small animal medicine) IN VETERINARY MEDICINE (SMALL ANIMALS) IN THE DEPARTMENT OF VETERINARY CLINICAL SCIENCES, University of Melbourne, Australia—Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, July 1).

CHAIR OF ELECTRICAL ENGINEERING—The Academic Registrar, Northampton College of Advanced Technology, St. John Street, London, E.C.1.

CHAIR OF ELECTRONICS—The Academic Registrar, Loughborough University of Technology, Loughborough, Leicestershire, quoting Ref. 12/AF.

KEEPER (preferably graduate with cartographical qualifications and administrative experience) OF THE MAP ROOM—The Director, Royal Geographical Society, 1 Kensington Gore, London, S.W.7.

LECTURER or ASSISTANT LECTURER (pure mathematician) IN THE DEPARTMENT OF MATHEMATICS—The Secretary, University College, Gower Street, London, W.C.1.

POSTDOCTORAL RESEARCH ASSISTANT IN THE DEPARTMENT OF CHEMISTRY for work under the direction of Dr. K. J. Morgan, on the determination of optical dispersion by spectroscopic methods—The Secretary, University of Lancaster, Bailrigg House, Lancaster.

READER (with at least five years teaching experience in light current and an adequate record of university and/or industrial research) IN ELECTRONICS AND TELECOMMUNICATIONS WITHIN THE DEPARTMENT OF ELECTRICAL ENGINEERING, University of Khartoum—The Secretary, Inter-University Council for Higher Education, 33 Bedford Place, London, W.C.1.

RESEARCH STUDENTS, RESEARCH FELLOWS and RESEARCH ASSISTANTS IN THE DEPARTMENT OF CHEMISTRY, for research into two broad fields, namely, electrochemistry and gas kinetics—Prof. Graham Hills, Department of Chemistry, The University, Southampton.

SENIOR RESEARCH ASSISTANT (with a degree or H.N.C. in electrical engineering or applied physics, or an equivalent qualification, and experience in electronics) IN THE MULLARD RADIO ASTRONOMY OBSERVATORY—The Secretary, Department of Physics, Cavendish Laboratory, The University, Free School Lane, Cambridge.

REPORTS and other PUBLICATIONS

A MEASURE OF REFORM

BY now time will have ceased to stand still at Oxford. The Franks Commission has at last reported, and the assimilation of its recommendations has begun. Other institutions will be closely concerned. Universities elsewhere, for example, will be affected if Oxford eventually adopts the new proposals on the admission of undergraduates. So will be the schools and their pupils. Then the British Government will be deeply interested in what the Commission has to say. Is Oxford a needlessly expensive way of teaching undergraduates? Or is it an especially good way of doing the job? Or is it both things at once?

The first thing to be said is that the Franks Report* is a most valuable public document. Its scope is enormous and it touches every aspect of university life, public and private. A reader can learn what kinds of schools send students to Oxford, and what proportion of the teaching staff takes dinner in hall at night. For months to come, no doubt, Oxford senior common rooms will be occupied in trying to tell which colleges are which in those anonymous tables which show how individual colleges pay, and otherwise reward, their Teaching Fellows. Then, running through the splendid language of the Report, there is the constant theme that Oxford is not an independent and autonomous university but a part of the educational system of the United Kingdom. Such qualities as the University can claim are but measures of its obligations. From this principle spring important egalitarian arguments —the view that the machinery for admitting students must be fair and seen to be fair, and that the richer colleges should be taxed to help the poorer ones. As an analysis of the present state of affairs, the Franks Report is entirely worthy of the great university it describes.

But will it accomplish what the critics say must be done? This, unfortunately, is not certain. In many ways the Report bears the marks of being an internal document—about Oxford by Oxford and, some will say, for Oxford. At several points the Commission has clearly been prevented by its familiarity with the existing state of affairs from contemplating seriously some extreme but effective remedies for acknowledged defects. In this spirit, for example, it has settled for a compromise on the appointment (by election) of the Vice-Chancellor. He is to be a full-time man at last, and is to be paid a salary; however, the reasons given for deciding to elect a new Vice-Chancellor every four years are so unconvincing that the accompanying proposals to strengthen the office of the Registrar are an inadequate assurance that in future it may sometimes be possible to tell who speaks for Oxford.

This is not to decry the whole Report. Most of the recommendations on the internal administration of the University are wise, and will make the university more effective as well as more efficient. If the proposals on the relationship between the University and the colleges are adopted, for example, a great many long-standing absurdities will be swept away. It is particularly sensible that all academic appointments should jointly involve the university and a college. The proposals on the finances of the colleges are courageous; the notion that essentially autonomous charitable institutions should regard their endowments as held in trust for the university as a whole will do much to change the character of Oxford for the better.

It is therefore all the more surprising that the Report should evade some crucial issues. The proposals on admissions, for example, are an awkward and probably unworkable compromise. It is understandable that the university should wish to attract more of the bright young people who do not at present spend an extra year in the sixth-form of a secondary school, preparing themselves for the competition. It makes very little sense, however, to say that there should be an alternative examination for those who are relatively unprepared. For if the new examination is fair, why should the majority of entrants to Oxbridge be required to spend an extra year at school on needlessly specialized study? And if selection is possible at all after a mere four terms of sixth-form work at school, why should not Oxford take pot luck with the system of university admissions that seems to provide most other universities with the undergraduates they need? Those passages in the Report of the Commission which urge the development of an entirely new system of admitting students to all British universities appear occasionally to suggest that Oxford has sought refuge in the delay there would certainly be in the design and development of an entirely novel system for entry to all British universities. The Commission seems to have lacked a sense of how the competitiveness of the Oxbridge entrance examinations distorts the balance of the curriculum in the schools. It also appears to have been surprisingly uninformed of the studies of the relationship between the universities and the schools now being carried out by the Schools Council and by the Committee of Vice-Chancellors.

The recommendations on the growth of Oxford are also disappointing. The Commission appears to have been needlessly dazzled by the social anthropology of the college system. The calculation is that a college with more than 500 members ceases to be viable. This leads to the conclusion that the student body (postgraduate and undergraduate) in 1980 or soon after may be 13,000, which is an increase of nearly a third more than the present size. It is also true that the growth now foreseeable will occur where it is most needed—there will be more postgraduates and more women. Yet Oxford will remain predominantly a university for the humanities. It is hard to see how some of the exciting developments now planned by scientists at Oxford can be successfully accommodated within the limits proposed by the Franks Commission. Fifteen years from now, Oxford could well be sorry that the Commission did not increase its estimate of science students by two thousand or so.

Picking holes in the Franks Report is going to be easy enough, but this does not imply that its publication will have no effect. On the contrary, it is bound to mark a turning point in the long development of Oxford, and the undertone of the Report makes it plain that the members of the Commission are aware of how eagerly their work is being awaited. After the criticisms of the Robbins Report, Oxford was a despondent place; now, three years later, the mood is very different. The University has

* See also page 667 of this issue of *Nature*.

come to recognize how its great virtues are not inseparably bound up with the out-dated practices which frequently invite criticism. The Franks proposals on postgraduates, for example, will be welcomed with enthusiasm in most colleges. So will be the administrative reforms intended to make the University more cohesive. In one sense the Franks Commission has already attained one of its principal objectives, for the public discussions which accompanied the process of collecting evidence has awakened the University to the opportunities of change. Even at All Souls, there will be a measure of delight.

CLOSING THE MOHOLE

THE future of the American project to drill a hole through the mantle of the Earth now seems in doubt. A week ago the Committee on Science and Astronautics of the U.S. House of Representatives jibbed at approving the new estimate of 28 million dollars for the cost of completing the Mohole. It remains to be seen whether the corresponding Senate committee will take the same view, but the prospects are not encouraging. For even if the Senate should consider that present costs are justifiable, the difference between the House and the Senate would somehow have to be reconciled before work could go ahead. Nobody will be surprised that those most closely associated with the Mohole project have been cast down by this latest twist in the long and tortuous history of this project.

Two separate questions arise. The wisdom of the House Committee's decision is, for example, open to question, chiefly because the Mohole project is now so far advanced. A technique for drilling deep holes in the ocean floor has been developed, and orders for the drilling barges have been placed. By cancelling now, the U.S. Congress will save only a proportion of the total cost of the Mohole. It is capricious, to say the least of it, for the politicians to pull hard on the purse-strings at this late stage. It would have been much more to the point if they had taken a hard sceptical look at the project four years ago, for there was then good reason for believing that the drilling programme was being pushed ahead too quickly, and with too little preliminary study. A more deliberate programme might have been easier to contain within the bounds of a public budget, and might have been more rewarding as well. But Congress cannot put the clock back to the beginning by a crude cancellation.

The second issue is even more alarming. Hitherto, Congress has not exercised to any important extent its constitutional right to arbitrate on the fine details of scientific programmes financed by public money. It is true that plans for building—and siting—big particle accelerators have usually been examined in detail by Congressional committees, and the National Institutes of Health have occasionally been showered with more money than they could usefully spend, but the great public agencies have usually been allowed to manage their own affairs within the framework of a budget agreed by Congress. Though the details of the programmes of the National Science Foundation have been examined by Congress in the process of accounting for the spending of public money, Congress has usually trusted the judgment of its scientific public servants on the disposition of these funds. On the face of it, the Mohole decision looks like a departure from this practice. It could be a dangerous precedent.

HELPING WISELY

International Aid

By I. M. D. Little and J. M. Clifford. Pp. 360. (London: George Allen and Unwin, Ltd., 1965.) Cloth 45*s*. net; Paper 25*s*. net.

INTERNATIONAL aid follows no general pattern; it is a tangled skein of threads beginning with the motives and objectives of the donor countries, often entangled with international organizations, and ending with a group of largely unco-ordinated projects in each of the recipient countries. In *International Aid*, Mr. Little and Mrs. Clifford have performed a valuable service in setting out and analysing the efforts of the more developed countries to help those less fortunate. They have had a difficult task, but have carried it out with considerable success. At times it may seem that they have tried too hard to equate quite different forms of aid, but the exercise has value in that it brings out very clearly the complexity of the problem.

In the early chapters, dealing with the history and quantity of aid, the authors describe its many forms; thus it may be a gift of money with or without any strings, or the supply of materials, equipment or services, or again it may be a loan at any interest rate from nil to the full commercial level and with time of repayment differing equally widely. Further, aid may be given on a bilateral basis or through one of the international agencies or organizations, to which many nations contribute, sometimes freely, at others with restrictions in the form of blocked currencies. The tables given in the book are valuable in that they bring together the available facts, but they should only be read in the light of the qualifications well set out in the text.

One point is clearly brought out, namely that British aid has been far from generous compared with that of some other countries. Moreover, it has not followed any set policy or shown the degree of understanding of the problems involved which might have been expected of the largest ex-colonial power. The limited total of aid has arisen from Britain's own financial difficulties, but the funds available might have been used more effectively if the administration at home and in the recipient countries had been better. Both in the Government departments in Britain and on the staffs of the High Commissions and the Embassies there have been few professional advisers either in the economic or the technical aspects of the work. The few were grossly overloaded so that they were compelled to dash from place to place, with no opportunities to make the intensive studies required for the best allocation of aid. The staffs of the High Commissions and Embassies were more concerned with political questions, as befitted their training, so that the immediate advantage of agreeing quickly to a local demand has been allowed to outweigh the long-term gain which would have resulted from a careful detailed study of the needs of a country. The politician and diplomat have had an unnecessary fear of being branded as 'neo-colonialist'. They have not appreciated that a newly independent country, while violently resenting any political interference, would welcome economic and technical help provided this did not involve long-term contracts of employment and left the final decision to the country concerned, even though the technical advice might point to only one conclusion. This willingness to accept technical help is well illustrated in the recently published report of the Agricultural Research Council of Central Africa, where, in spite of all political differences, Rhodesia, Zambia and Malawi join with the United Kingdom and the United States in financing the work of an international staff.

One of the greatest needs of the less developed countries is for technical assistance. The staffing of a new and highly technical project is often completely beyond the means of a developing country. Help is required to get the project started and in the training of the men who will ultimately

run it. All too often funds which have been made available are left unused for long periods because the necessary staff cannot be found. In desperation men who are not really suited for the work may be recruited with resulting disappointment in the recipient countries.

Here, too, Britain has failed to grasp the opportunities offered. In agriculture and other branches of food production, there were men in the colonies with special training and valuable experience. With independence these men had, in most cases, to choose between short-term contracts or leaving with a generous compensation, which directly or indirectly came out of aid the colonies received. Many left and retired or took up other work unrelated to agriculture in the developing countries. If they could have been recruited into a corps of specialists with permanent career prospects they would have been invaluable in the fight to increase food production. The developing countries would have been saved the cost of compensation and so, to that extent, have required less aid. The loan of these men would have provided most valuable help at a relatively low cost. It is only recently that efforts have been made to meet this need by adding supernumerary posts to the universities, research institutes and the advisory services. Unfortunately, very many of the potential recruits have been lost.

The book includes a most interesting chapter on the principles of aid giving. We are all inclined to be smug about the aid we provide, convincing ourselves that our intentions are altruistic. Yet much of the aid given has, for its objective, either commercial or political advantage. This may be direct or it may arise from the economic development of the country receiving the aid.

Another chapter of special interest is that dealing with the co-ordination of aid administration. Anyone who has been concerned with this work must be conscious of the lack of co-ordination among the international agencies and between the individual donor countries. There is an equal lack of co-ordination between the different ministries in the recipient countries. The authors discuss the many aspects of this complex problem, bringing into focus the doubts and fears which are shared by all those concerned with giving and receiving aid.

This book is one to buy and read and then to retain for reference. It is not easy reading but the effort is well worth while. It should be compulsory reading for all politicians, for civil servants in the appropriate ministries including the Treasury and for our representatives in the less developed countries. W. K. SLATER

BIOPOIESIS

Current Aspects of Exobiology

Edited by G. Mamikunian and M. H. Briggs. Pp. xi+420. (London and New York: Pergamon Press, Ltd., 1965.) 120*s*.

CURRENT Aspects of Exobiology consists primarily of papers delivered at a meeting on exobiology held at the Jet Propulsion Laboratory during February 26–28, 1963. Four papers presented at this meeting were not available for publication and the editors have replaced them with other reviews. The contents of the volume are best described by the titles of the various chapters: "Investigation of Organo-Chemical Evolution"; "Organic Remains in Meteorites"; "Micro-organisms of Middle Precambrian Age from the Animikie Series, Ontario, Canada"; "The Survival Capabilities and the Performance of Earth Organisms in Simulated Extraterrestrial Environments"; "The Possibility of a Primordial Lunar Life"; "Possibilities of Life on Mars"; "Life-Detection Experiments"; "Biological Contamination of the Planets"; "The Radio Search for Intelligent Extraterrestrial Life"; "Trends and Problems in Exobiology".

References are included in each chapter, and at the end of the volume is a lengthy list dealing with "considerations of the existence of life on other planets and for the universe and in origin of life" plus some material on the "physical and chemical nature of the planets" considered relevant.

The field of exobiology is a very exciting area of contemporary research, dealing as it does with what is probably the most important and intriguing problem to mankind—the origin of life and its possible existence on extraterrestrial bodies. Regrettably the present volume does not do justice to the field and will prove of only limited usefulness to the scientific community. The long time delay between preparation of the material and publication of the book results in much of the material being outdated and in many important recent developments being omitted. Moreover, the editing has been somewhat loose with an unfortunate lack of balance and unevenness of treatment. Thus one of the most intensively studied areas, the nature of organic matter and organized elements in carbonaceous chondrites, has only sixteen pages devoted to it, whereas one of the two longest chapters, sixty-four pages in length, deals with a highly controversial theory that oceans existed on the Moon for extensive periods of time and that a lunar life originated therein. While Chapter 2 is devoted solely to carbonaceous chondrites, an extensive discussion of the same topic is contained in Chapter 5. Similarly, a portion of the material discussed in "Possibilities of Life on Mars" is again repeated in "Life-Detection Experiments". Several chapters are marked by a subjective approach which is apparently motivated by the desire that life has originated externally and independently of Earth. This is quite notable in Chapters 2, 5 and 6, and detracts significantly from these discussions. Finally, the merits of the extensive bibliography must be questioned since there is no indication of the extent of the literature search, either in terms of journals and books or in terms of years. Presumably it is intended to appeal to the scientist working in the field, but because of these shortcomings he could not rely on the competence of the list and would perforce carry out his own detailed literature search.

Despite these critical comments, the volume will be a useful addition to a serious exobiology library because of the presence of excellent articles on certain areas, notably organo-chemical evolution (Part 1 of Chapter 1); pre-Cambrian micro-organisms (Chapter 3); life-detection experiments (Chapter 7); biological contamination of the planets (Chapter 8); and the search for intelligent extraterrestrial life (Chapter 9). However, the spotty nature of the coverage and the high price will discourage most scientists and many libraries from adding it to their collections. D. G. REA

MOLECULES AND EVOLUTION

Internal Factors in Evolution

By Lancelot Law Whyte. Pp. xxiii+81. (London: Tavistock Publications Ltd., 1965.) 18*s*.

INTERNAL Factors in Evolution is a timely book. There has been an undercurrent of thought in the minds of scores, perhaps hundreds, of biologists, including many geneticists, over the past 25 years, suggesting that the picture drawn by modern genetical studies is insufficiently adequate and comprehensive. Such doubts have crystallized around the problem of the randomness of mutation, the directiveness imposed by the persistence of cultural preferential trends over many generations and latterly by the rise of molecular biology with its evidence for highly complex organization at a subsidiary level. Thus J. B. S. Haldane (1959), towards the end of a life devoted mainly to research in genetics, was himself forced to the conclusion that "it is almost certain that facts will

be discovered which will show that the theory of natural selection is not fully adequate to account for evolution".

The essence of Whyte's book is the conclusion that the conditions of biological organization restrict, to a finite discrete spectrum, the possible avenues of evolutionary change from a given starting point. The nature of life limits its variation and is one factor directing phylogeny. Thus the mutations of which the consequences reach the Darwinian test have already been sifted by an internal selection process. This internal selection restricts the directions of evolutionary change by internal organizational factors. The author says "there may be no mutations which can be fully ascribed to chance", and he quotes Bachelard (1953) that there is implicit in quantum mechanics a structuring tendency for complex systems to form more complex forms of ordering. He then suggests, though obviously with some doubts, that this could perhaps be the basis of internal selection. Thus, the attempt is made to complement the Darwinian principle of external adaptive selection by a new type of selection acting directly on changes inside the organism at the molecular and chromosomal levels. Under this principle, random mutations are subjected to a selection process dependent on their compatibility with the internal organization and processes of the organism, before the adult faces environmental competition. It is his view that biological order, co-ordination and organization have equal importance with random statistical competition and that this concept is, in a radical philosophical sense, complementary to Darwin's principle and has, therefore, significant implications for the psychological and social sciences as well as for biological sciences. Medawar (1960) is quoted as having suggested that there is in systems of polymers a 'repetitiousness' or tendency towards elaboration, so that ever more complex sets of genetical instructions are offered for trial and that this may provide a basis for advancing complexity; and I think the general response for molecular biologists to Whyte's views will be favourable.

The book is brief, trenchant and profound. The fact that it may not contain any ideas which are absolutely new is no weakness; rather it is in this that much of its strength lies. Whyte is to be congratulated on having brought together and unified in discussion a number of ideas that have been somewhat on the fringe of biological thought in recent years. All who are interested in the fundamental ideas of unity, ordering, complexity, adaptiveness and directiveness—and that is to say almost all biologists—should read this book. Once they have read it they are unlikely, whatever their response, to forget it. They may disagree on how good the evidence is for some of the conclusions and on how far ideas put forward have been adequately covered by earlier writers. They can hardly argue that the problems raised are other than topical and fundamental.

W. H. THORPE

ADSORPTION FROM SOLUTION

Adsorption from Solutions of Non-Electrolytes

By J. J. Kipling. Pp. xii+328. (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1965.) 73*s*.

THE understanding of adsorption from solution requires not only a knowledge of the dispositions of, and interactions between, the solution molecules in a surface phase, but also a knowledge of the corresponding situation in the bulk of the solution. Solution and liquid state theory are not, however, in a well-developed state, at least as compared to that for gases, and if only for this reason we may expect adsorption from solution to be a difficult field of investigation. The understanding of adsorption on to solid surfaces from solution requires in addition an intimate knowledge of the solid surface and its interactions with the liquid phase components. The complexities of such systems are obviously immense and it is scarcely surprising that adsorption from solution on to solids has the appearance of being a rather neglected subject. *Adsorption from Solutions of Non-Electrolytes* by J. J. Kipling, is the first book of its kind and reflects accurately the present state of the subject.

This book is almost entirely concerned with adsorption on to solids. There are sections on liquid–vapour and liquid–liquid interfaces, but these are included more for purposes of comparison than for their intrinsic interest. Apart from this limitation, the book is very comprehensive and is based on the extensive experience and work of the author in this field. The early chapters describe the methods of investigating adsorption while the later ones are devoted to specific systems, and the results that are now available to us. The latter are presented systematically. Five chapters deal successively with adsorption from completely miscible liquid mixtures, from partially miscible liquids, of gases, solids and polymers from solution and of adsorption from multicomponent systems. Among the remaining chapters are descriptions of the kinetics of adsorption and the thermodynamics of adsorption. The book contains a considerable amount of data and probably all the important references. The material is well presented and very readable.

Although it will be primarily of interest to research workers in surface chemistry, there are many sections which can readily be used for undergraduate instruction. In my opinion, this is an excellent and much-needed book and is to be wholeheartedly recommended. The only disappointing feature is the price.

D. A. HAYDON

ELECTRONS AND HOLES AT THE SURFACE

Semiconductor Surfaces

By A. Many, Y. Goldstein and N. B. Grover. Pp. xvi+496. (Amsterdam: North-Holland Publishing Company, 1965.) 110*s*.

THE advent of the transistor after the Second World War did more than revolutionize the electronics industry. It set solid-state physics on its feet. It provided, in the study of germanium and silicon, the first really critical test of the electronic theory of solids, one of the triumphs of quantum theory. It stimulated research into many aspects of the solid state. And it presented, in the *p–n* junction, the first really simple example of an electrified double layer.

The great success of *p–n* junction theory has rested largely on two simplifying features: the very low concentrations of the charged particles, and the fact that the electrons and holes move in the same medium on both sides of the junction. In much of the recent research on silicon and germanium surfaces these two advantages have been retained. Electrons and holes in the semiconductor remain, as a rule, the only mobile charge carriers. The bending of the bands at the surface, even in extreme cases of inversion or accumulation, is rarely so great as to introduce degeneracy. The amount of bending, expressed by the surface potential or the electric field normal to the surface, can be controlled at will by using an external electrode (the field effect) or by chemical means. Passage of current parallel to the surface is used to determine excess densities of electrons and holes, and to measure surface mobilities, which are lower than in the bulk. These and other techniques have been elaborated and applied with considerable success to silicon and germanium surfaces, and it is fair to say that we have by now reliable and detailed models both for clean surfaces and for real (oxidized) surfaces, at least up to and including the fast states on the inside of the oxide. The slow states on the outside present a more difficult problem.

Semiconductor Surfaces is the first text-book to deal comprehensively with this new and thriving branch of solid-state physics, and should not be confused with a number of conference symposia bearing similar titles. It will certainly be in great demand. The authors, already well known for their original research in the field, have produced a well-integrated and readable account of the present state of the art, both theoretical and experimental. After a masterly résumé of the theory of bulk semiconductors, which many readers will value for its own sake, there is a mainly experimental chapter on surface preparation and its effect on the lattice structure. Then there are two theoretical chapters: in the first the authors describe the space-charge region in some detail in terms of solutions to the Poisson–Boltzmann equation, using their own improved system of normalized co-ordinates, and displaying graphically the more important results; the second gives the quantum theory of surface states and the associated statistics. Chapters 6 and 7 describe experimental methods, with main emphasis on the field effect, though surface recombination and various emission phenomena are dealt with at some length. The next chapter gives the theory of electron and hole transport at the surface, with experimental results. A final long chapter contains a critical account of our present knowledge of silicon and germanium surfaces.

The presentation is excellent. There are remarkably few errors or misprints. Ample use is made of diagrams and graphs. The text is well documented, the final chapter alone containing more than 400 references. If the book has a fault it is to be found perhaps in its supreme air of competence and confidence. One is left with the feeling that here is a subject thoroughly explored, put in order and offered up to technology on a plate: of course there is much to be done, but the conceptual framework is now established. Is it? What are its limitations? How accurate is the Poisson–Boltzmann approximation? Surely discreteness of charge is important in a narrow surface channel. We are left wondering. Image forces are barely mentioned, and are assumed to exist only outside the surface. No distinction is drawn between elemental and ionic semiconductors. The more enquiring reader will need to look beyond this book for a view of the future. But most of the students, engineers, and experimental physicists to whom it is addressed will find it a mine of information and instruction, an invaluable introduction to the literature, and a real pleasure to read. J. I. CARASSO

GOOD ENOUGH TO EAT

Principles of Sensory Evaluation of Food

By Maynard A. Amerine, Rose Marie Pangborn and Edward B. Roessler. Pp. x+602. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) 156*s*.

A POLISH proverb claims that fish, to taste right, should swim three times—in water, in butter and in wine. The early efforts of the basic scientists in the food industry were directed at improving the preparation, preservation, and distribution of safe and nutritious food. Our memories of certain foodstuffs eaten during the Second World War suggest that, although these might have been safe and nutritious, they certainly did not taste right nor were they particularly appetizing in appearance or smell. This neglect of the sensory appeal of foods is happily becoming a thing of the past. Indeed, in 1957 the University of California considered the subject of sufficient importance to warrant the setting-up of a course in the analysis of foods by sensory methods. *Principles of Sensory Evaluation of Food* grew out of this course, and is the first of a series of monographs on food science and technology to be published by the Academic Press. The authors hope that it will be useful to food technologists in industry and also to others engaged on research into the problem of sensory evaluation of foods.

The scope of the book is well illustrated by the chapter headings: "The Sense of Taste"; "Olfaction"; "Visual, Auditory, Tactile, and Other Senses"; and "Factors Influencing Sensory Measurements". There are further chapters on panel testing, difference and directional difference tests, quantity–quality evaluation, consumer studies, statistical procedures (including design of experiments), and physical and chemical tests. An attempt has clearly been made to collect every possible piece of information which might be useful, more than one thousand five hundred references being quoted. As a result, the book seems at first sight to be an exhaustive and critically useful review of the literature. This it certainly is, but this is by no means its only achievement, for there are many suggestions for further lines of research, and the discursive passages are crisply provocative of new ideas and new ways of looking at established findings.

Of particular interest is the weight given to the psychological aspects of perception, both objectively and subjectively. The relation between stimuli and perception is well covered, and includes a valuable discussion of the uses and disadvantages of the Weber fraction in the evaluation of differences. It is interesting to find that in spite of many attempts to separate and define the modalities of taste, nothing better has been achieved than the familiar classification into sweet, sour, salty and bitter. Nor is there as yet any clear-cut evidence of the physiological nature of the taste stimulus. With regard to smell, systems of classification are of little value because of the extraordinary sensitivity of the nose and because the response to the stimulus is so subjective. The authors suggest that a classification based on the size, shape and electronic status of the molecule involved merits further investigation, as does the theoretical proposition that weak physical binding of the stimulant molecule to the receptor site is a necessary part of the mechanism of stimulation.

Apart from taste and smell, there are many other components of perception of the sensations from food in the mouth. The basic modalities of pain, cold, warmth and touch, together with vibration sense, discrimination and localization may all play a part, as, of course, does auditory reception of bone-conducted vibratory stimuli from the teeth when eating crisp or crunchy foods. In this connexion the authors rightly point out that this type of stimulus requires much more investigation, suggesting that a start might be made by using subjects afflicted with various forms of deafness. It is, of course, well known that extraneous noise may alter discrimination, and the attention of the authors is directed to the work of Prof. H. J. Eysenck on the "stimulus hunger" of extroverts and the "stimulus avoidance" of introverts[1]. (It is perhaps unfair to speculate, not that the authors do, that certain breakfast cereals rely on sound volume to drown any deficiencies in flavour, or that the noisier types are mainly eaten by extroverts.)

One very minor criticism of the book is that almost nothing is mentioned concerning the effects of dentures on perception of food sensation. With the world population of old people increasing, it would be thought that the masticatory status, in terms of deficient natural dentitions or full dentures, and its relationship to food selection or rejection, would be of importance to food technology. There are many accounts of investigations on these lines in the dental literature which could have been included.

The authors believe that scientific investigations of the sensory analysis of foods must be based on a thorough knowledge of sensory physiology and an understanding of the psychology of perception. This book gives ample evidence that they can justify their belief. Although they modestly say that it is directed primarily at food technologists, there is no doubt of its value to many others. There is much to interest, inform and even surprise workers

in many other fields, both in the basic sciences, including the behavioural and the clinical. The binding, printing, paper and general layout of the book are unusually good, and it is structurally tough enough to stand up to the rather traumatic life of the frequently handled laboratory reference book. Although its price in Britain may seem high, the quality and quantity of the information contained in it should make cost a very secondary consideration.

INSECT MYCOSES

Pilzkrankheiten bei Insekten

Anwendung zur Biologischen Schadlingsbekämpfung und Grundlagen der Insektenmykologie. Von Dr. Erwin Müller-Kogler. Pp. xvi+444. (Berlin und Hamburg: Verlag Paul Parey, 1965.) 98 D.M.

THE study of entomogenous fungi, for long one of the better known by-ways of mycology, has during recent years been attracting increasing attention because of deepening interest in the biological control of harmful insects. One of the earliest investigations on entomogeneous fungi is a landmark in the history of microbiology. In the 1830's Agostino Bassi, an Italian lawyer turned farmer, after prolonged and ingenious experimentation, established the concept of pathogenicity by proving that the muscardine disease which then ravaged the silkworm industry was caused by the fungus later named in his honour *Beauveria bassiana*. Interest in *B. bassiana*, which is pathogenic for many kinds of insects, has persisted, and there are more references to it in *Pilzkrankheiten bei Insekten* than to any other fungus. Index entries to *B. bassiana* occupy four of the seven columns of the general index devoted to the genus *Beauveria*, which is only surpassed by the combined eight columns of entries for *Entomophthora* and *Empusa*, two genera which, as the author notes, taxononomic mycologists now consider should be united.

If the first book on entomogenous fungi in general, that is to say, on fungal parasites, symbionts, and saprophytes of insects, has yet to be written, *Pilzkrankheiten bei Insekten* is nevertheless most welcome. It breaks new ground in applied entomogenous mycology by bringing together a comprehensive account of attempts to control insect pests, both experimentally and in the field, by the use of fungi and of the underlying theoretical considerations.

The stage is set in Part 1 (pp. 1–62) in which efforts to control insect and mite infestations of crop plants and forest trees during the period 1937–63 are concisely summarized. Some seventy examples of attempts to control diverse pests by the use of more than twenty different species of fungi are assembled, and in addition there are a dozen instances of the use of *B. bassiana* combined with DDT or other insecticides which frequently gave better control than that by either component.

Part 2 (pp. 63–146) includes sections on fungi, the diagnosis of insect mycoses, and the isolation and culture of the fungi involved, but only clues to other works are given for their detailed identification. Consideration is also given to virulence and techniques for the bulk production of spores, and methods for their application are considered in some detail.

To control outbreaks of fungal disease is sometimes difficult but to induce infection, particularly epidemics, under field conditions and at will is even more difficult. This is reflected in Part 3 (pp. 147–347), in which aspects of pathogenesis such as the infection process and the subsequent progress of the pathogen and its effects on the host, host resistance, and the factors in the external environment—particularly those which constitute 'weather'—are dealt with, and for certain of these environmental factors the data are conveniently tabulated. Another table lists fungal hyperparasites recorded on entomogenous fungi and finally there is a brief consideration of epizootics.

The whole work is well documented and there is a 40-page bibliography.

G. C. AINSWORTH

HOMAGE TO LITTLEWOOD

Papers presented to J. E. Littlewood on his 80th Birthday Edited by J. D. Weston. (Proceedings of the London Mathematical Society, Third Series, Vol. 14A.) Pp. v+314. (Oxford: Clarendon Press; London: Oxford University Press, 1965.) 80*s*. net.

PROBABLY no account of the most famous collaboration in the whole field of mathematical discovery will ever be written: the writings of Hardy contain only the most cursory of asides, and Littlewood's fascinating essay on his own mathematical education ends with the tantalizing words: "I soon began my 35-year collaboration with Hardy". Burkill (*Mathematical Gazette*, 38, 47) gives, on the authority of Harald Bohr, the axioms on which the partnership rested, including that which asserted that if one wrote a letter to the other, the recipient was under no obligation to reply to it, or even to read it. Speculation is bound to be ill-informed and possibly impertinent; but on looking again at Hardy's early papers, published before the joint work began, it is possible to feel that, sparkling as they are, they are not quite "in the Hobbs class", to use Hardy's own phrase for supreme excellence, whereas those of the partnership, which began about 1913 with papers on the summability of series and Tauberian theorems, proceeding to the great sequence of memoirs on problems in '*partitio numerorum*', undoubtedly are. Wiener's dichotomy, classing Hardy as the man of clarity and original ideas, Littlewood as the man of power and indomitable persistence, is an oversimplification, in so far as it suggests that each had to supply something the other lacked. The partnership was *sui generis*, and defies dissection; but because this volume is in homage to Littlewood, we may fairly quote Hardy's remark, that he knew of "no one else who could command such a combination of insight, technique and power".

Twenty-six research papers, by friends and colleagues, including many former pupils, ranging over wide domains of mathematics, form an impressive tribute to a great mathematician and a great mathematical teacher. There were no histrionics in Littlewood's Cambridge lectures; the solution of difficult problems appeared a simple matter, until a close investigation in the hope of determining just how the miracle was worked suggested that the lecturer had brought his own rock-climbing skills into the lecture-room, and had exhibited there, too, the almost instinctive ability to detect the precise hand- or foot-hold from which the optimum leverage could be derived. Comment on the process was not withheld; and novices, perplexed by the sets of zero measure which cropped up as exceptions in many real-variable theorems, could be grateful for the emphasis on the informal principles, that every measurable set is nearly a sum of intervals, every integrable function is nearly continuous, and every convergent sequence of functions is nearly uniformly convergent. When these lectures were published in book form, the informal comment, the motivations of the arguments, the care to isolate and emphasize the crux of a proof, contributed substantially to guiding the reader through an intricate domain, in which the content and style prompted Rado to say that reading the book "induces an exalted state of mind closely akin to that experienced when listening to a great symphony or string quartet".

Papers presented to J. E. Littlewood on his 80th Birthday, printed in the best Clarendon Press style, makes a worthy present from the London Mathematical Society to not the least distinguished of its many famous presidents.

T. A. A. BROADBENT

OXFORD AND THE FRANKS REPORT

THE University of Oxford will now know the worst The Report of the Commission of Inquiry under Lord Franks has now been published (May 12, 1966, Clarendon Press). Externally, the chief consequences will be new policies on the admission of undergraduates, on the balance between undergraduates and graduates and between the arts and the sciences. For the rest, the report recommends important changes in the administration of the university including a proposal to centralize the machinery for making decisions without losing the appearance, and some of the reality, of democracy; the taxation of richer colleges for the benefit of the poorer, and the re-organization of academic life in such a way that the separation between the colleges and the university is less pronounced than it has been in recent centuries. It is also proposed that All Souls should have three years "to set its house in order", and in particular to decide how to spend its excess investment revenue. Apart from being a vehicle for specific proposals for change, the Franks Report is also a fascinating and frequently an eloquent exercise in the sociology of a university which is, for better and worse, without compare.

The Franks Commission was created by Oxford in February 1964, after the criticisms of Oxford which appeared in the Robbins Report. The terms of reference were wide, and the Commission was required to assess "the part which Oxford plays now and should play in the future in the system of higher education in the United Kingdom, having regard to its position as both a national and an international university". Among the questions specifically referred to were the administration of the University and the arrangements for the appointment of a Vice-chancellor, the relationship between the University and outside bodies including those from which public funds are obtainable, the relationship between the autonomous university and the substantially autonomous colleges, and matters of finance, staffing, curriculum, selection, examination and postgraduate teaching. The Commission collected evidence throughout 1964, and its work included special surveys, based on questionnaires, of matters such as the academic needs of undergraduates and the work-load of the academic staff. The members were Lord Franks, Sir Lindor Brown, Mrs. J. Floud, Sir Robert Hall, Miss M. G. Ord, Mr. M. Shock and Mr. J. Steven Watson.

The Commission readily accepts a good many of the criticisms made of Oxford in the Robbins Report and elsewhere. Thus it accepts that "an effective administrative system which combines democracy with decision is the first need of Oxford. Unless this is secured, other reforms cannot be undertaken with real hope of success". It accepts "that the mists through which Oxford permits itself to be seen can obscure much more than its statistics". The result, the Commission says, is the prevalence of misconceptions which "arise from Oxford's failure to take the trouble to explain itself". At the outset, the Commission also notes the criticisms that "Oxford is a privileged place", that its academic efficiency is low, that the university as a whole pays too little attention to postgraduate teaching and that the college system, which emphasizes the importance of undergraduate work, exacerbates the neglect of research.

Admissions to Oxford

The Franks Commission says that the problem of selecting undergraduates has been complicated since the end of the Second World War by the great increase in the number of young people seeking entrance to universities and by the wish of schools other than independent and direct grant schools (which are partly dependent on public funds but independently governed) to prepare students for universities. The existing procedure for selecting candidates, based on an entrance examination administered by the colleges, is said to be valuable in itself but to be attended by undesirable consequences. For one thing, the entrance examination supposes that candidates will have spent more than two years in the sixth-form of a British school and will have been provided with knowledge extending well beyond the Advanced-level examination taken by all senior school leavers.

Though the Commission does not accept that Oxford is biased against pupils from maintained schools, and though it can point with satisfaction to the steady increase in the proportion of those admitted to Oxford from maintained schools (19 per cent of male entries in 1938 and 40 per cent in 1965), the Commission does accept that "Oxford is not yet receiving applications from candidates coming from these schools on the scale that the number of prospective university entrants would warrant". The result, says the Report, is that Oxford is impoverished in the quality of its students and their diversity, and that it is exposed to the "suspicion of privilege and social injustice". This difficulty is likely to be increased by the growth of comprehensive schools. "The low application rate from the maintained schools is evidence that Oxford is lacking efficiency as it fishes for promising talent in the national pool: from this point of view the present entrance examination is neither academically successful nor socially just."

What is to be done? The Franks Commission argues that it will be impracticable and undesirable for Oxford to maintain a selection system independent of that used by other British universities, especially as its proportion of all university entrants in Britain declines from the present 7 per cent. But A-level examinations are not a good basis for selection, because they are not designed for university entrance, because university selectors do not play a part in their design and because A-level marks "are not necessarily a good guide to promise in university work". In the long run, the Commission holds, there will have to be a nation-wide system for selecting undergraduates for entry to British universities, but it also says it would not help if Oxford were to throw in its lot with the other universities in the immediate future, and were to rely on the machinery of the Universities Central Council on Admissions (UCCA), because that would "increase the already undesirable pressure which university requirements at A-level puts on the work of the schools". Thus it is that the Franks Commission recommends "that the long-term solution lies in the adoption of a new common admissions system by all universities, and we recommend that Oxford should work towards the initiation of plans for the reform of the admissions system on a national scale. What is wanted is a completely fresh look at the problem of university selection. We think that Oxford is well placed to take an initiative in this matter".

Recognizing that all this cannot come about overnight, the Franks Commission has proposed an interim revision of the Oxford entrance procedure, principally to meet the fear that the university is not sufficiently accessible to pupils who do not spend a third year in the sixth form at their secondary schools. Briefly, it is proposed that there should be two parallel entrance examinations, one for candidates who have spent more than two years in the sixth form, and another for those who offer themselves a year earlier in the school chronology, and who are sufficiently mature (17·5 years in the December of the academic

year in which entry is sought). The Franks Commission reckons that some 10 per cent of the present intake of undergraduates at Oxford would at present qualify under such a procedure, and it suggests that the university as a whole should aim at selecting some 20 per cent of its intake by means of an examination taken before A-level. (The Commission sets its face against a fixed quota.)

Closed scholarships should be abolished, and open scholarships and exhibitions reduced in number so that no more than 10 per cent of the undergraduate population of any college hold scholarships, and in such a way that the value of all awards to undergraduates should be worth £50 a year, and should be dependent on evidence of satisfactory work year by year.

Modest Growth

If the Commission has its way, the undergraduate population will grow modestly in the years immediately ahead, and the postgraduate population will grow much more quickly. Table 1 summarizes recent experience of the growth of the student population and the predictions of the Franks Commission.

Table 1

	1928–29	1948–49	1965–66	1980–85 (est.)
Undergraduates				
Arts, etc.	3,402	4,679	5,080	5,000–5,500
Science	714	1,480	2,518	3,250–3,750

All students	4,559*	7,294*	9,824	13,000 (est.)

* A few students who cannot be classified as undergraduates or graduates are omitted.

Predictions about the future size of the postgraduate population are based partly on the recognition of a growing need of postgraduate teaching and partly on the arguments of faculties at Oxford which have provided the Commission with estimates of their own futures. Thus the Commission recommends a growth of the postgraduate population from 23 per cent at present to at least 30 per cent.

The comparatively small increase in the total size of the university is held, in the Report, to be necessary if the collegiate structure of the university, and the advantages thereof, are to be retained. A college, the argument goes, should not be so big that "no one person can hope to know all the members", which is said to be roughly equivalent to the rule of thumb that no college should have more than 500 members, students and senior members. The Franks Commission also holds that the university would lose its cohesion if the number of colleges were to grow without restraint.

The Commission is far less specific about the directions in which such expansion as it recommends should take place. It directs attention to the plans for expansion which already exist in the fields of science and technology, but points out that changes in the numbers of students following courses of different kinds have come about as a result of the policies of individual colleges on the admission of undergraduates. Obviously the Franks Commission is anxious that there should in future be a better co-ordination of these separate tendencies, apparently through the Council of the Colleges, the formation of which is intended to serve the whole cause of co-ordinating college policy.

Conditions of Work

The Oxford tutorial system is the most surprising of the many aspects of academic life at Oxford that the Franks Commission would like to see changed. Sensibly, however, the Report points out that no system of tutorials can at present cover the whole of an undergraduate syllabus without an excessive expenditure of time and effort. It also accepts a great deal of the argument from university teachers to the effect that present concern for the tutorial system entails too great a burden on the academic staff, and recommends that no student should be expected to write more than one tutorial essay a week during term (though he may attend more than one tutorial in the company of others).

The proposals on the conditions of service for academic staff may do much—if they are eventually accepted by the university—to simplify the movement of academics out of and into Oxford. The complications of the present system under which teachers may be appointed either by colleges or by the university, though sometimes by both, are to be removed by a common system of appointment under which university and colleges share responsibility. The arrangements proposed would create the category of "Fellow-lecturer", appointed jointly by the university and by one of the colleges, and required to teach for "up to fourteen hours" a week. Some Fellow-lecturers would owe their first allegiance to the university, and others to a particular college, but none would be entirely in one camp. Stipends would vary a little—Franks thinks not much—according to the college. University readers would increasingly be freed from undergraduate teaching to spend time on postgraduate instruction and supervision, and should have salaries of up to £3,250 a year, with an extra £400 for those retaining the teaching duties in colleges. The Franks Commission would also create more teaching posts at the professorial level, and though there is no suggestion of abandoning the system of a fixed salary (of £4,100) for all professors, it is planned that a professor who is also head of a department can retain his special responsibility allowance without having to do the administration that would normally be involved.

A measure of the extent to which Oxford teachers are said to be overburdened with teaching at present is the calculation of the Commission that the university would have to (and should) recruit a further 182 teachers to bring the size of its teaching staff to the level used as a national standard by the University Grants Commission. Further regularities should flow from the set of detailed proposals that would ensure that college Fellows are equitably and fully charged for the benefits in kind which attachment to a college may sometimes bring.

For the rest, the Report of the Commission makes several recommendations about the improvement of the co-ordination of teaching programmes, for postgraduates and undergraduates alike. Examinations are to be co-ordinated, and continuity preserved from one year to another; arrangements made to see that all university posts should carry with them the automatic right to an M.A. degree and the right that stems from it to take part in the government of the university; the Queen will be asked to forgo her prerogative to appoint the Regius professors at Oxford (with the exception of the canons of Christ Church); and all colleges will be expected to obtain university consent before making senior research appointments.

The Report is scornful of All Souls and of the successive attempts of that college, spread out over the years since the Royal Commission on Oxford in 1922, to spend the whole of its investment income now amounting to close on £250,000 a year. The report suggests that All Souls should aim to spend at least £100,000 on academic activities of its own, and that the college should present a plan to this end to the University within three years.

On general administration and finance, the Report suggests the creation of networks of interlocking committees for general and academic purposes. Within them, the Vice-Chancellor would become more powerful than at present, though it is not proposed to appoint permanent Vice-Chancellors at Oxford but merely to extend the term of office from two years to four. Arrangements are to be made for taxing the richer colleges to support the poorer, which will make it easier for the latter to take on their full share of postgraduate students.

THE ORIGIN OF CONTINENTS

By J. W. SALISBURY and L. B. RONCA

Lunar-Planetary Research Branch, Air Force Cambridge Research Laboratories, Laurence G. Hanscomb Field, Bedford, Massachusetts

THE origin of continental nuclei has long been a puzzle. Theories advanced so far have generally failed to explain the first step in continent growth, or have been subject to serious objections. It is the purpose of this article to examine the possible role of the impact of large meteorites or asteroids in the production of continental nuclei.

Unfortunately, the geological evolution of the Earth's surface has had an obliterating effect on the original composition and structure of the continents to such an extent that further terrestrial investigations have small chance of arriving at an unambiguous answer to the question of continental origin. Paradoxically, clues to the origin and early history of the surface features of the Earth may be found on the Moon and planets, rather than on the Earth, because some of these bodies appear to have had a much less active geological history. As a result, relatively primitive surface features are preserved for study and analysis.

In the case of both the Moon and Mars, it is generally concluded from the appearance of their heavily cratered surfaces that they have been subjected to bombardment by large meteoroids during their geological history[1,2]. Likewise, it would appear a reasonable hypothesis that the Earth has also been subjected to meteoroid bombardment in the past, and that very large bodies struck the Earth early in its geological history.

The largest crater on the Moon listed by Baldwin[1] has a diameter of 285 km. However, if we accept the hypothesis of formation of some of the mare basins by impact, the maximum lunar impact crater diameter[1] is probably as large as 650 km. Based on a lunar analogy, one might expect several impact craters of at least 500 km diameter to have been formed on Earth. By applying Baldwin's[1] equation (7–1*A*), the depth of such a crater should be about 20 km. Baldwin admits that his equation gives excessive depths for large craters so that the actual depth should be somewhat smaller. Based on the measured depth of smaller lunar craters, a depth of 10 km is probably a conservative estimate for the depth of a 500 km impact crater. Baldwin's[1] equation (7–11*A*) gives the depth of the zone of brecciation for such a crater as about 75 km. The plasticity of the Earth's mantle at that depth makes it impossible to speak of "brecciation" in the usual sense. However, local stresses may be temporarily sustained at that depth, as shown by the existence of deep-focus earthquakes. Thus, short-term effects might be expected to a depth of more than 50 km in the mantle.

Even without knowing the precise effects, there is little doubt that the formation of a 500-km crater would be a major geological event. Numerous authors have considered the geological implications of such an event. Donn *et al.*[3] have, for example, called on the impact of continent-size bodies of sialic composition to form the original continents. Two major difficulties inherent in this concept are the lack of any known sialic meteorites, and the high probability that the energy of impact would result in a wide dissemination of sialic material, rather than its concentration at the point of impact[4].

Gilvarry[5], on the other hand, called on meteoroid impact to explain the production of ocean basins. The major difficulties with this model are that the morphology of most of the ocean basins is not consistent with impact, and that the origin and growth of continents is not adequately explained.

We agree with Donn *et al.*[3] that the impact of large meteorites or asteroids may have caused continent formation, but would rather think in terms of the localized addition of energy to the system, rather than in terms of the addition of actual sialic material.

The formation of a 10 km deep crater would result in a decrease in pressure of approximately 2,500 atm.[6]. The effects of fracturing down to a depth of more than 50 km would strongly decrease the pressure locally at greater depths. It is impossible to speculate in detail on the sequence of events which followed the impact, but it is

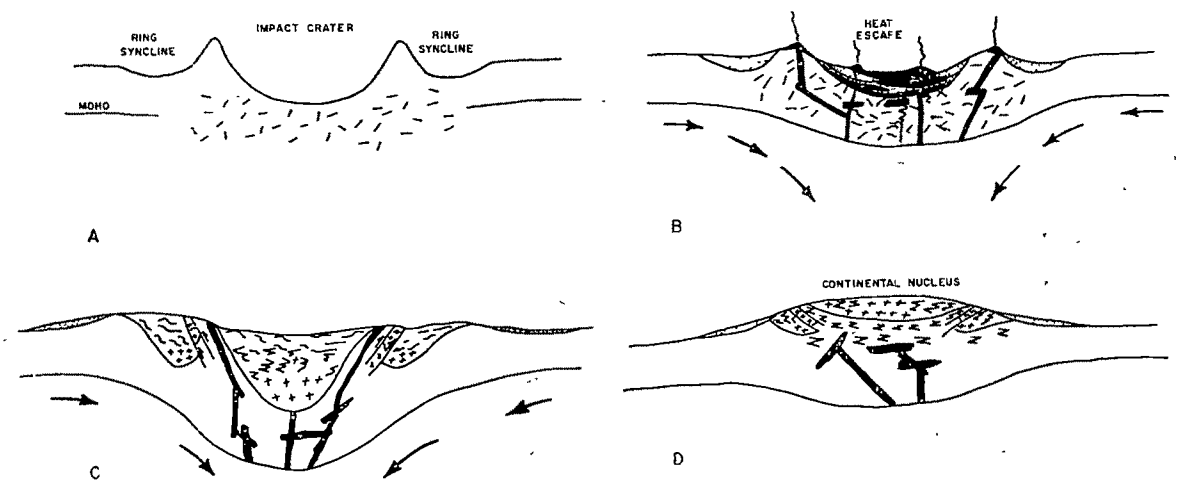

Fig. 1. Proposed mechanism of formation of the continental nucleus. *A*, Immediately after the impact. *B*, Shortly after a new Mohorovičić discontinuity may be formed, deeper than before. Heat released at the surface causes cooling and downflow in the mantle. *C*, Sinking and compression caused by the downflow. *D*, When the heat loss is terminated, downflow stops and the continental nucleus rises. Downflow may restart at the borders, resulting in geosyncline formation and continental growth

reasonable to assume that considerable volcanic action would result from the combination of sudden release of pressure and crustal fracturing[7]. Erosion of crater rim material and volcanism should then jointly fill the crater basin and circumferential syncline, which are typical features of large impacts, with low-density sediments and volcanics (see Fig. 1). As a result of this density differential, the entire complex would be isostatically uplifted to form a continental nucleus. It is of interest to note, in this regard, that the apparent age of the lunar maria (3·6 billion years[8]) is close to that of the oldest continental rocks[3].

Once the continental nucleus has been formed as suggested here, subsequent continental growth could occur in a number of ways. The temperature at a depth of 10 km early in the geological history of the Earth is not known, but 200° C is probably a very conservative estimate, considering the present-day extrapolated temperature at this depth of about 300° C. Before the formation of the continents, convection currents in the mantle were also probably distributed in some simple geometric pattern[9]. The impact would have caused the exposure at the surface of material originally at a temperature of at least 200° C. Even without volcanism, such a structure would be a powerful geothermal sink, conceivably able to modify the convection currents. The most logical modification would be the downflow of the cell immediately under the crater, with all the geosynclinal properties of such a phenomenon[9]. When sediments were sufficiently thick to result in a thermal blanket, the downflow would shift to the edge of the newly formed "protocontinent". From here on, the process would continue as described by Vening Meinesz[9]. Fig. 1 shows diagrammatically such a process.

Kennedy's theory[10], in which the Mohorovičić discontinuity is held to be a phase change, also explains the process by which a geosyncline would sink and accumulate a great quantity of sediments, provided that a basin is present in the first place. Under this theory, the first effect of sediments deposited in the basin and ring syncline of the continental nucleus would be to increase the pressure under them, without any significant increase in temperature. This would cause the Mohorovičić discontinuity, which must have initially migrated downward in response to the reduced pressure attendant on crater formation, to move upward toward the surface. The resulting increase in density would cause the area to sink. As more sediments were added to the sinking trough, their low thermal conductivity would finally result in an increase in temperature, which would cause a downward migration of the Mohorovičić discontinuity. The resulting decrease in density would result in a general uplift of the area. The uplift would create a topographic gradient at the edge of the lifted area, where sediments would be again deposited, thus perpetuating the process.

Whatever the precise history of continental growth, it would appear that the localized additions of energy to the Earth's crust, which would result from the impact of large meteorites or asteroids, could produce continental nuclei through the formation of impact structures. Convection currents and/or the migration of a phase change boundary would assist in the formation of a nucleus, as well as in subsequent continental growth. Other mechanisms could, however, function just as well in continent formation, given the initial localized addition of energy resulting from an impact.

DDT RESIDUES IN ADELIE PENGUINS AND A CRABEATER SEAL FROM ANTARCTICA

By PROF. WILLIAM J. L. SLADEN

Department of Pathobiology, Johns Hopkins University, Baltimore, Maryland

AND

C. M. MENZIE and W. L. REICHEL

Bureau of Sport Fisheries and Wildlife, Patuxent Wildlife Research Center, Laurel, Maryland

IN the 20 or more years of use of DDT for insect control in the United States, traces of this pesticide or its breakdown products have become ubiquitous. Even fish in remote streams and those that spend their lives on the high seas have been shown to contain residues[1]. It has been speculated that DDT residues are universally distributed[2].

An opportunity to examine the pesticide content of animals living in the most remote part of the globe came during a visit to the Antarctic. This article reports on the pesticide content of Adelie penguins and a crabeater seal collected at Ross Island, and relates this content to the biology of the animals and to the possible distribution routes of the contaminants.

Samples of liver and fat were collected (by W. J. L. S.) during the third week of February 1964 from six adult male Adelie penguins, *Pygoscelis adeliae*, and one young male crabeater seal, *Lobodon carcinophagus*, at Cape Crozier, Ross Island (77° 27′ S., 169° 14′ E.). The two species were selected because they rarely range beyond the limits of the pack ice and can therefore be considered true residents of the Antarctic region. They both feed on crustacea, as do most of the whalebone whales. The rookery where the penguins were collected is the largest (about 300,000 breeding birds) of the most southerly breeding places for the Adelie, and its location in the Ross Sea is as remote from pesticide-contaminated portions of the world as could be hoped for.

The penguins analysed (Table 1) were selected to represent extremes of physiological condition[3]. Parents actively feeding their chicks are not accumulating body fat (our specimens weigh 4·0 and 4·5 kg, and their blubber is 2 mm thick), but at the end of the season when the chicks are grown the Adelies gorge with food at sea and rapidly

Table 1. QUANTITIES OF DDT AND ITS METABOLITES FOUND IN SIX ADULT MALE ADELIE PENGUINS AND A YOUNG MALE CRABEATER SEAL COLLECTED FROM CAPE CROZIER, ANTARCTICA, FEBRUARY 16–20, 1964

† Fat was from the lower abdomen in all the penguins and from beneath the skin (blubber in the seal).
‡ Parent arrived from sea with a full stomach of shrimp and a small quantity of fish.
§On the beach waiting to depart for sea. Stomach was empty.

gain weight and fat deposits (6·0–6·5 kg and blubber 10 or 12 mm thick) prior to the moult. The birds come to land or stay in the pack ice to moult and fast for about 3 weeks, losing 45 per cent of their body-weight[4]. Our post-moult bird weighed 2·9 kg.

A sample of fat was also taken from an emperor penguin, *Aptenodytes forsteri*, which had been collected by Dr. Edward Wilson in July 1911 during the British Antarctic Expedition's Winter Journey and left, partly exposed to wind and snow, for the past 52 years on the floor of a stone igloo[5] a few miles from the Cape Crozier emperor rookery.

The greatest care was taken to avoid contamination from clothing and hands when the Adelie or seal specimens were collected. Dissecting instruments and the glass containers used for transport were thoroughly cleaned, then rinsed with acetone. Samples were individually wrapped in aluminium foil, placed in one glass jar per animal and sealed with aluminium foil lining the cap. The specimens were frozen within 2 h of collection and remained so until chemical analysis.

No special precautions against contamination were taken with the emperor penguin material as it was not collected with subsequent pesticide analysis in mind. A flipper with attached frozen axillary fat was removed from the 52-year-old carcass by knife and bare hands and stored in a plastic bag. Like the other specimens, the emperor fat remained frozen until analysed.

Residue analyses were made at the Patuxent Wildlife Research Centre (by C. M. M. and W. L. R.) by electron-capture gas chromatography, with confirmatory identification by thin-layer chromatography. The samples were prepared by grinding, then drying with sodium sulphate. They were then extracted for 7 h in 'Soxhlet' apparatus with petroleum ether, then 7 h with isopropanol–hexane (1: 1); extracts were carried separately thereafter. Acetonitrile–hexane (1: 1) partitioning was used to clean up the petroleum ether extracts; hexane partitioning for the isopropanol–hexane extraction; elution was through a 'Florisil' column (3: 1 hexane–benzene). Gas chromatography was carried out with a 'Jarrell-Ash' gas chromatograph fitted with an electron capture detector; column, 5 per cent *SE*-30 on 80/90 mesh 'Anakrom *ABS*' in 0·25 in. × 44 in. glass column, nitrogen pressure 30 lb./in.^{2}, range 10^{-9} amp; column temperature 150° C, injector temperature 195° C. Thin-layer chromatography was also carried out as a confirmatory measure on eluates from all samples combined. Readings were made on 200 × 200 mm plates coated with aluminium oxide *G* (0·25 mm thick) and activated at 130° C for 0·5 h. Some fat remained, and the combined sample was spotted on four plates in 10 μl. aliquots. 10 μl. of the sample was also placed on standards to compensate for the distortion of R_F values. The plates were developed with hexane, but only the standards were sprayed with Mitchell's silver nitrate solution and exposed to ultra-violet light. That portion of the plates corresponding to DDE, DDD, and DDT was removed with a vacuum zone collector, extracted and re-read by gas chromatography. The total of 11·8 μg of DDE from individual samples agreed closely with the amount (12·4 μg) found after combining the samples. The eluate was again concentrated, then developed, sprayed. and read by thin-layer chromatography. DDE and DDT were observed, but the amount of DDD was insufficient.

Separate portions of the fat and liver of the same individuals were also analysed at the Wisconsin Alumni Research Foundation. The samples in this case were prepared by low-temperature drying and grinding with sodium sulphate. Extraction was for 8 h in 'Soxhlet' with ethyl-ether and 'Skelly *B*'. Acetonitrile partitioning was used for cleaning up, followed by elution through 'Florisil' column with ethyl-ether and 'Skelly *B*' (5 : 95). Gas chromatography was carried out using a 'Barber-Colman' 5,000 series gas chromatograph with an electron-capture detector; the column consisted of acid- and base-washed and silenized 'Chromport *W*' coated with 5 per cent Dow Corning 200 (12,500 centistokes) in 0·25 in. × 48 in. column, nitrogen flow 75 c.c./min, column temperature 210° C, injector temperature 240° C, detector temperature 230° C.

All samples from the six Adelie penguins and the crabeater seal contained minute traces of DDT and its metabolites ranging from 13 to 115 parts per billion in liver and 24 to 152 parts per billion* in fat (Table 1). No DDT products were detected in the emperor penguin fat, which came from a bird killed over 30 years before the world-wide use of DDT, nor were residues of other chlorinated hydrocarbons found in any of the specimens. Analyses by the Wisconsin Alumni Research Foundation also showed the presence of DDE and DDT in comparably minute traces ranging from 11 to 64 parts per billion in liver and in fat. These results are remarkably close, considering the minute quantities involved. Moreover, the portions tested by the two laboratories were different samples from the same individuals, not sub-samples of a single-blended preparation.

The Adelie (No. 6163) that had undergone considerable post-moult weight loss still contained residues that were high in concentration (though not in total quantity) by comparison with others in the series. This indicates that the extensive metabolism of fatty tissue that occurs during moult does not result in the complete elimination of the pesticide residue from the fat or liver. This is what would be expected on the basis of experimental studies with rats in which animals subjected to enforced weight loss through food deprivation showed increased DDT concentration in the fat that remained, thus indicating that the rate of loss of fat exceeded the rate of loss of pesticide[6].

* U.S. billion; 1×10^9.

On the basis of present knowledge, the quantities of DDT in the penguins and seals would be judged an unlikely hazard to them. DDT residues in living animals collected in the United States independently of known treatment programmes vary in amount from quantities similar to those in our Antarctic specimens to amounts thousands of times greater[7]. One investigation of DDT residues in human body fat in the United States showed approximately 7 p.p.m.[8].

With so little available information on the distribution of DDT in Antarctic wildlife, we can only speculate on its mode of transport to the area and its incorporation in the ecosystem. Several possibilities can be considered.

Local contamination from man is unlikely. DDT is not used in Antarctica, though it is possible that a certain amount is carried on fur and woollen clothing. Evidence against direct contamination from clothing during collection comes from the fact that the emperor penguin fat was negative despite few precautions during collection. Moreover, with one exception, the positive specimens showed a higher proportion of residues in the fat than in the liver, as would be expected under conditions of low chronic exposure. Contamination from faulty handling would have been more likely to have given equal quantities in fat and liver.

Waste disposal at the United States and New Zealand stations at Hut Point, Ross Island, about 50 miles from Cape Crozier, is another possible source of some DDT contamination of the local marine life. A total of more than 1,000 men stay at these stations in summer and 200 in winter. Packing material, food waste, old clothing, and frozen human excreta are dumped on the sea ice and liberated to the sea during a brief period in late summer when the ice breaks up.

A conservative approximation of the quantities of DDT discarded in food waste can be made on the basis of the normal content of DDT residues in the United States diet. This amount has been estimated to be 0·184 mg/man/day[9]. If food waste is assumed to equal half the total food consumed, then feeding a group of 1,000 men for 100 days would provide 9 g of DDT residues. A portion of ingested DDT will also be eliminated in the faeces, but the amounts eliminated at such low levels of intake have not yet been estimated. However, there would be rapid dilution in the water of McMurdo Sound of any traces in the waste from such a small human population. It is, perhaps, also significant that no other chlorinated hydrocarbons were detected in the penguins and seal, yet they would be liberated in minute quantities, like DDT, in food waste.

Another possibility is that the DDT residues reached the South Polar regions by air currents. DDT recovery from the air has been reported in the United States by the U.S. Public Health Service[10], and in several unpublished investigations. There is accumulating evidence to indicate that bacteria, fungal spores, strontium-90, and even land arthropods[11] have been transported to Antarctica by air. The dilution of the air would be so great, however, that we consider it unlikely that this is the principal source of contamination of the fauna. Two samples of ice were examined by the Southeast Water Laboratory, Public Health Service, Athens, Georgia[12]. One sample represented glacial ice from Byrd Station (80° S., 119° W.) deposited prior to 1940 and the other, glacial ice deposited more recently. Neither of these samples contained traces of any pesticide. DDT would have been detected if it had been present in concentrations of as little as 0·05 part per billion.

It is also possible that DDT might have been carried into Antarctic waters by ocean currents. The penguins and seals feed in the Antarctic surface current, which, moving northwards, sinks below the warmer sub-Antarctic water at the Antarctic Convergence. Although there will be mixing on the Convergence, it would be difficult for contaminants to spread directly southwards against the Antarctic surface current. Contaminated water would be more likely to gain access to the Antarctic by way of the warm deep current which, passing upwards between the Antarctic intermediate current and the Antarctic bottom water, is responsible for the upwelling of nutrients in the Antarctic region. This warm deep current originates chiefly in the north Atlantic Ocean. It has been estimated, however, that it would take many years for particles to reach the Antarctic from the north Atlantic where it is assumed the pollution is highest. But, as Deacon[13] points out, not all the warm deep current originates from the north Atlantic. Much of it must be formed from the Indian and Pacific Oceans and also from mixing between northward and southward movements in the sub-Antarctic region. Thus, it would be possible for pollution to reach the Antarctic surface water by way of the warm deep current, though it would be expected to take longer to come from the northern than from the southern hemisphere.

Concentration in the food chains would provide the next step in the build-up of pesticide residues. The Adelie and crabeater occupy the third trophic layer of a typically simple Antarctic food chain. Adelies from Cape Crozier feed their young partly on small fish, but mostly on *Euphausia crystallorophias*[14], the dominant shrimp in the neighbourhood of the Ross Ice Shelf and the Victoria Land coast. Farther off the coast, *crystallorophias* is replaced by the most abundant of all the euphausids, *E. superba*, a circumpolar species that occurs predominantly in the east to west Antarctic surface current, but which overlaps with *E. frigida* in the west-wind drift almost to the Antarctic Convergence. In fact, Mackintosh[15] has pointed out that the ten species of southern *Euphausia* overlap (as do other components of the marine fauna) in their distribution in characteristic zones to the sub-tropical Convergence. In addition to the overlap in horizontal distribution, which shows remarkably little seasonal change, there are seasonal and diurnal vertical migrations of these and other plankton which lead them away from the Antarctic surface water into the warm deep current and therefore into the most likely source of contamination. For this reason, the Adelies and crabeaters are more likely to pick up DDT and concentrate it in their tissues from traces in *E. superba*, or even *E. frigida*, when they are feeding in the pack ice away from land.

Finally, there is the possibility of direct contamination of Antarctic waters, and subsequent concentration in the food chains, from the breakdown of the vast hordes of marine organisms, including whales and birds, which move freely across the Antarctic Convergence and into temperate zones. Whales do most of their feeding south of the Convergence, but they move north in the austral winter. Of the bird species, the Arctic tern, *Sterna paradisea*, the giant petrel, *Macronectes giganteus*, the sooty shearwater, *Puffinus griseus*, the Wilson's petrel, *Oceanites oceanicus*, and other species have extensive migrations from the Antarctic and sub-Antarctic to the harbours and coastal waters of most countries of the southern hemisphere, or to the North Atlantic and Pacific Oceans[16]. For example, the Wilson's petrel, reputed to be one of the most abundant birds on earth, breeds around the Antarctic and on its islands, then moves during the austral winter into the Indian, Pacific and Atlantic Oceans. It can be seen in great numbers scavenging off the eastern coast of North America between April and September. A few months later it will be back in Antarctica feeding on *Euphausia superba*. These are but a few examples to emphasize two important points. There are enormous changes in biomass in the surface waters of the South Polar regions according to the seasons, and the southern oceans are linked directly and rapidly with different parts of the world by these and other migrating scavengers and carnivores.

The Antarctic fieldwork was supported by a grant from the National Science Foundation. We thank the Office of Antarctic Programs, National Science Foundation and

the U.S. Navy Support Force, Operation Deep Freeze, for their assistance. We are indebted to Dr. L. F. Stickel for co-operation and advice.

GUESSING AS A FORM OF INTELLIGENT BEHAVIOUR

By Dr. R. T. GREEN*
Ministry of Education and Culture, Port of Spain, Trinidad
AND
B. G. STACEY
Lanchester College of Technology, Coventry

WE have recently been reminded by Hammerton[1] that guessing is not always random. This is scarcely contestable. What is, perhaps, of more interest is Hammerton's contention that the type of correction for guessing often made in intelligence tests of the multi-choice variety is inadequate. He offers evidence in support of the thesis that guesses have a better than random probability of being right and that therefore "It can pay to guess". The implication seems to be that guessing in this context is a mild form of delinquency and is not sufficiently penalized by applying the usual correction formula. Two points arise and need clarification. The first has to do with item uniqueness, while the second involves more fundamental considerations.

To illustrate the argument, and to provide data, Hammerton uses a modified version of Shipley's vocabulary test. With this kind of test it can hardly be denied that on balance it pays to guess when in doubt. Two sorts of reasons account for this. First, the subject may have good grounds for rejecting some of the possibilities, either because he knows their meanings and is sure that they are not synonymous with the word specified, or because they are the wrong part of speech, or for some similar reason. If only one of the distractors is of this form, then a subject's chance of hitting the right answer is not $1/n$ but $1/(n-1)$, and so on. Secondly, as is widely recognized, there is a continuum between ignorance and certainty which may favour guessing in certain circumstances. In vocabulary tests this influence will favour guessing unless the distractors have been specially chosen to mislead the unwary. However, the broad assertion that this influence must favour guessing overlooks the factor of item uniqueness. If we choose items carefully, we can easily demonstrate that guessing raises or lowers scores, or leaves them unaffected.

The following multi-choice item is a good example:

CONDIGN means the same as
BLAME, MEET, PEPPERY, PRAISEWORTHY, SLANDER.

Unless the subject actually knows the right answer he is more likely to choose one of the distractors. The main point of the argument is that it is possible to produce items of this kind and to engineer the distribution of guessing probabilities in any way that takes the fancy. It is a matter of interest to examine why this should be so.

In this particular example we have engineered the situation by:

(*a*) Using a word that is in any case little known.

(*b*) Using a target word that has a far more common meaning than the alternative meaning that corresponds to CONDIGN.

(*c*) Choosing distractors that are plausible. For example, CONDIGN has about it a similar ring to CONDEMN, and so may easily be thought akin to any word involving value judgments.

(*d*) Confusing the subject still further by not giving clues as to whether he should be looking for a verb, adjective or noun. Only PEPPERY and PRAISEWORTHY are clearly adjectives; BLAME and SLANDER can operate as nouns or verbs; while MEET in its common form is a verb, although it is as an adjective that it provides a synonym for CONDIGN.

An experiment has been carried out following the procedure of Hammerton. A vocabulary test was presented to subjects who were also asked to give, with each response, an assessment of their own feelings of confidence or doubt. The subjects—forty in number—were all adults with a good educational background. The test was a modified version of the vocabulary part of Shipley's self-administering test[2]. The even-numbered items were used with the addition of an extra distractor to each item, so that a subject had to choose the correct word from among five words. The CONDIGN item was added to the end. The null hypothesis was that each word on the CONDIGN item would be chosen an equal number of times, and that any observed differences would merely be chance variations. The prediction was that those who 'guess'—those who express some 'doubt' or are 'very doubtful'—on this item would tend to choose one of the distractors rather than the target alternative; in other words, less than 20 per cent of the subjects would choose MEET.

All the subjects were doubtful about the CONDIGN item, and the following results were obtained.

NUMBER OF SUBJECTS CHOOSING TARGET WORD AND DISTRACTORS

Meet	Distractors
1	39

A one-tailed binomial test[3] indicates $P < 0.001$, so that the prediction is confirmed.

* Seconded from University College, London.

So, if we were to apply the usual guessing correction to a test composed of items of this type, the standard correction for guessing would be too punitive. A subject who knew none of the answers, but who valiantly guessed, would be likely to get rather less than 20 per cent right, and would therefore end up with a negative score. And serve him right, some may say. But does it? Here we come to the second main point—one of principle that leads on to far more interesting issues.

When as test constructors we somewhat arbitrarily designate one of the alternatives as 'correct', we risk making the disconcerting discovery that we are less intelligent than some of the people we presume to test. With a dictionary in one hand and a fertile imagination controlling the movements of the pen in the other, test constructors must feel pretty confident in their ability to spot the winner. Subsequent item analysis can be a chastening experience. A typical example came to light in the course of constructing a vocabulary scale that would discriminate reliably among university students. The test constructor (R. T. G.) thought it would be a good idea to include TURGID as an item, on the grounds that some people might easily confuse it with TURBID. TURGID means BOMBASTIC according to the dictionary. However, it would seem that most intelligent people remain unaware of this, and item analysis revealed that it took a relatively low-grade intellect to choose BOMBASTIC as a synonym, MUDDY being much preferred by those scoring high on the test as a whole. Nowadays, TURGID is most often associated with the phrases of TURGID prose or TURGID style. In this context it easily slips into use as a synonym for CONGESTED or OBSCURE, and hence MUDDY. If English is defined as the language used by contemporary intelligent and educated English-speaking people, then the writers of dictionaries would appear to be out of touch with a number of developments in current usage.

The lover of Shakespeare's language may deplore the fact that DISINTERESTED is often misused; particularly since IMPARTIAL has so few synonyms. Nevertheless, we must come to terms with the idiosyncrasies of a vital language that has somehow managed to transform SANCTION into its own antonym. In the interests of public safety, perhaps less regret need be felt when INFLAMMABLE, which is currently in the process of being transformed, is eventually superseded by the Americanized FLAMMABLE. The pronunciation of BANAL provides a related case in point, and that of QUESTIONNAIRE another just as interesting in its own way.

It should be pointed out that the orthodox methods of item analysis do not always reveal weak items of this kind. As a rule, each item is called right or wrong, and all the wrong responses are lumped together for the purpose of computing a bi-serial r or whatever other statistic is used to correlate the item response with either an internal or an external criterion. This method can easily conceal the fact that among the responses designated wrong by the constructor there can lurk one alternative (or even more) that would show up a good deal better than the officially correct response if the more valid distractor were to be designated right and the computation re-run. By lumping together all the so-called wrong responses, the highly intelligent subjects choosing the most valid response(s) are swamped by the subjects who select the really hopeless distractors. Only by sorting responses to each item into as many groups as there are possible responses is it possible to discover which response is, in fact, the most valid. Using this technique, the alternatives can be ordered in terms of validity and the fact that the difference between right and wrong is one of degree can be brought out. In an item analysis of this kind performed on the Cattell III test (Buros[4], p. 440), a disturbingly high proportion of the items were found to be either non-discriminating or wrongly keyed.

Granted, then, that right and wrong are to be considered operationally, rather than as *ex cathedra* pronouncements on the part of the test constructor, we come back to the intelligent subject faced with choosing from among a number of alternatives the one most likely to be scored right. He may, of course, be perfectly sure of the answer and, as is well known, there is usually a significant positive correlation between subjective confidence levels and the probability of being correct. However, the intelligent may be less than certain. In these circumstances we may ask:

(*a*) Is he entitled to guess?

(*b*) Should he be penalized for wrong guesses, and, if so, to what extent?

(*c*) Is it more intelligent to guess than to pass over the item?

The first question will bear little discussion. All answers are in a sense guesses; even if the subject is certain he is right, there is no guarantee that his confidence is justified. If we attempt to make an ethical issue of this—that guessing is in some sense dishonourable—we shall find ourselves forced into a peculiar moral posture. "When in doubt, do nothing" is the injunction, which is a strange request to make of a subject, and may fairly be interpreted as "Have no doubts".

The two remaining questions are inter-related and come closer to the heart of the matter. It has been suggested by Hammerton[1] that guessing in these circumstances is analogous to what goes on in signal detection experiments. This is a perfectly tenable point of view, particularly if the concept of 'gambling' between 'Type I' and 'Type II' errors as used by Swets *et al.*[5] is emphasized. A 'Type I' error occurs when we reject the null hypothesis although it happens to be true; a 'Type II' error occurs when we accept the null hypothesis although it happens to be false. Scientists, for the most part, adopt the convention that it is preferable to accept a high risk of 'Type II' errors, rather than vice versa. There are, however, exceptions to this general rule which are far more germane to real life situations.

For the present purposes, however, it may be more profitable to go to game theory for a more powerful theoretical framework within which to analyse this type of guessing behaviour. In their book, *A Study of Thinking*, Bruner, Goodnow and Austin[6] show how the concept of a pay-off matrix, stemming from the work of von Neumann and Morgenstern[7], can be used to analyse problem-solving behaviour in psychological terms. With intelligence tests we are dealing with problem-solving behaviour of a special kind, and what may not have been fully appreciated until now is that there is a pay-off matrix associated with guessing in this context, even though the matrix is rarely defined clearly or made explicit by the test constructor. This, however, is scarcely the fault of the subject, who has to do the best he can in a relatively unstructured situation.

If we state explicitly how a test is to be scored, the subject can then make rational decisions about his guessing strategies. We can say, where there are five alternative answers to each item, that the subject will be credited with one point for every item correct, and debited a quarter of a point for every item wrong. Using this standard form of correction for guessing, the subject knows that on balance it should pay to guess. If his guesses really are random, then he will, in the long run, neither gain nor lose. If, as is generally the case, subjective confidence and probability of being right are correlated, then on balance he should come out on the right side, which is perfectly reasonable. The ability to make good guesses is the same as the ability to pick the right answer, the difference being purely one of degree. Any subject who in these circumstances refuses to guess (or who refuses to choose, short of subjective certainty) either lacks the intelligence to draw the appropriate conclusion regarding the pay-off function for himself or—if he can draw the conclusion but cannot bring himself to act on it—may be said to be acting irrationally.

An alternative form of explicit instruction would be to tell a subject that he will not be penalized in any way for guessing. Again the intelligent subject will be sure not to leave any item unanswered.

But what of the more common form of instruction that leaves the question of guessing vaguely undetermined? Here the subject has to construct a pay-off matrix for himself by divining what the probable scoring procedure is, and play his game accordingly. This form of instruction will favour the adventurous, even reckless, individual who enjoys risk-taking and believes in making the most of poorly structured situations. The more restrained, pedantic type of person will find himself at a disadvantage and will, almost inevitably, be penalized for his timidity. And this, it may be argued, is what life is like. The person who refuses to take unnecessary risks, no matter how favourable the pay-off function, is left behind in any race—for money, power, prestige or the more human satisfactions associated with the needs for companionship, warmth and affection. In a city, the person who waits until the street is entirely clear of traffic before crossing the road will certainly minimize the risk of being struck down by a vehicle, but he will cross very few roads.

So it would seem that most intelligence tests as presented are, in this matter of guessing, more like personality tests. Furthermore, a case can be made for the paradox that they are more effective as intelligence tests precisely because they do possess this characteristic of being a kind of personality test. This is not a new idea. It is expounded by Wechsler[8] in his theory of non-intellective intelligence, and in which he attacks the widespread assumption that personality and intellectual factors belong to different domains. Wechsler shows that there are personality components integral to mental functioning. In effect, he argues that the level at which an individual functions as an intelligent creature depends, among other things, on his emotional economy. The person who behaves stupidly because of his emotional difficulties is still behaving stupidly. Whether or not he can overcome these difficulties and function at a higher level is a question comparable with that of the extent to which he can overcome an early environmental deficit of an intellectual kind.

This brings the argument back to the two questions with which we began. We can answer the second, more or less adequately, by saying that it is usually more intelligent to guess than pass over an item, but that everything will depend on the pay-off function. It would be simple enough to devise a pay-off function that would penalize subjects so heavily for wrong answers that it might pay to refuse to answer all the items. Existing tests do not, however, go to such extremes, and it is doubtful whether any intelligence test is made more effective as a discriminator by the use even of the standard correction for guessing. Indeed, there are grounds for arguing that test instructions should be more explicit about the penalties for guessing, so that the intelligent subject would be given an opportunity to derive the pay-off function and use his rational powers to overcome whatever personality factors might otherwise inhibit his performance. Without this information he is left in the invidious position of having both to allow for his own personality variables, and to divine the emotional attitude of the test constructor towards guessing.

OBITUARIES

Prof. L. R. Wager

PROF. L. R. WAGER, professor of geology and Fellow of University College, Oxford, from 1950, died suddenly in London on November 20, 1965, at the age of sixty-one.

Lawrence Rickard Wager was born at Batley, Yorkshire, on February 5, 1904, and educated at Leeds Grammar School. He proceeded to Pembroke College, Cambridge, where he graduated in 1926 with first-class honours in geology in the Natural Sciences Tripos. The award of a Goldsmiths' Company Studentship then enabled him to work at Cambridge for three years under Dr. Alfred Harker, chiefly on the mineralization and metasomatism of the Whin Sill.

This early interest in petrology was to continue for the rest of his life and to earn him a world-wide reputation as a leading authority on the petrogenesis, mineralogy and geochemistry of igneous rocks. Wager was primarily a field geologist, however, in that he advocated and applied the principle that an interpreter of the Earth's history should see the evidence for himself, and in this he was not the sort of man to content himself with a limited objective. During his remarkable life he scaled the higher reaches of Everest, explored the Greenland Ice-cap, mapped 35,000 km^2 of rocks in one Arctic year, produced the most important account of an intrusive complex known in petrological literature, and established and directed, at Oxford, a particularly advanced geochemical research group dealing chiefly with radiometric age and isotope studies on rocks and minerals. The hallmark of a first-rate geologist is the ability to trace and find his evidence on any part of the Earth's surface, to investigate the material using advanced laboratory techniques, and then to co-ordinate the minute details and translate them often in terms of the vastness of the Earth's framework and its time-span. Wager showed more than just the ability to do this, for he was outstanding in each field.

In 1929 he was appointed to a lectureship at the University of Reading, and the period between then and the outbreak of war saw him on several expeditions as both geologist and climber. At Cambridge he had been president of the Mountaineering Club, and in 1930 he was chosen by Gino Watkins to go to East Greenland as a member of his British Arctic Air Route Expedition. The three hazardous exploratory journeys in which Wager participated included a scientific reconnaissance of 200 miles of the treacherous Angmagssalik–Kangerdlugssuaq coast, a 250-mile return sledge journey to relieve the inland Ice-cap weather station, and a 360-mile return journey to climb the highest point then attained in the Arctic (Mount Forel). In 1932 he continued his geological reconnaissance investigations with the Scoresby Sound Committee's Second East Greenland Expedition, and went there again in 1934 with Dr. Charcot in the *Pourquoi Pas?* In 1935, with Augustine Courtauld and others of the British East Greenland Expedition, he climbed the highest mountains in the Arctic (the Watkins Mountains). With two Eskimo families he then wintered in the remote Kangerdlugssuaq region, together with his brother as botanist (Dr. H. G. Wager) and both their wives, and, in the company of W. A. Deer, he conducted a year's

geological survey of about 35,000 km² of Tertiary volcanic country (Southern Knud Rasmussens Land) and a remarkably detailed study of the associated plutonic complexes. He returned to the region in 1953 as joint leader of the East Greenland Geological Expedition, and at the time of his death had obtained financial support for a large-scale second geological expedition, which he was to have led jointly with Prof. W. A. Deer (Cambridge) in 1966 and 1967.

Wager's skill on rock and ice was already well known when, in 1933, he joined Hugh Ruttledge's Everest expedition. On May 30 of that year, hampered by the beginning of frost-bite and with the oxygen supply from the air reduced to one third of normal, he and Wyn Harris reached 28,100 ft. in an assault on the summit. "Knowing these men as I do, they would not turn aside from a climb within the limits of the possible", wrote Ruttledge, but they were still capable of bringing back an ice-axe dropped by Mallory in 1924 and, in Wager's case, specimens from the limestone cliff that had barred their way to the summit. Wager wrote papers on the structural and geomorphological features of the Everest region, and on the fossilized organisms that lay in rocks uplifted nearly six miles above the seas in which they had once lived.

In 1939, after a number of papers by Wager on the Tertiary volcanic rocks of the region, he and W. A. Deer published a memoir on the petrology of the Skaergaard intrusion of East Greenland (*Medd. om Grønland*). Few treatises have had such an impact on the science of petrology, and even to-day it comprises one of the standard references on gabbroic layered intrusions. This large body of Tertiary igneous rock, exposed in the mountains and fjords of Kangerdlugssuaq, was shown by the authors to have formed by the slow cooling and crystal fractionation of about 500 km³ of basalt magma in a subsurface, funnel-shaped magma chamber. They proposed that as the crystals of a varied mineral assemblage formed, they were transported by magmatic convection currents to the floor of the chamber and deposited as successive layers. The near-perfect arrangement of the layers, exposed over about 7,500 ft. of thickness, provided the investigators with successive crops of minerals in equilibrium with the contemporary liquids over a relatively wide temperature range (starting at about 1,150° C), and Wager and Deer provided a searching account of the textural, mineralogical and chemical variations, as well as a hypothesis, widely accepted to-day, on the mechanisms of formation of layered intrusions.

In 1944, Wager went to Durham as professor of geology after war service as an officer in the Royal Air Force. He had been engaged on aerial photograph interpretation, advising troops on Arctic warfare, and sailing in Arctic seas with the Murmansk convoys, and was mentioned in dospatches.

At Durham and, since 1950, at Oxford, he continued his profitable researches into the petrology of the Skaergaard intrusion. Joined by colleagues and a host of postgraduate students, the researches fell chiefly into three categories: mineralogical studies on the silicate, oxide and sulphide minerals; geochemical studies on major and trace elements and on radioactive isotope ratios in the rocks and minerals; and calculations aimed at an understanding of the crystallization history of the intrusion. He was also concerned with investigations into the petrology of other layered intrusions in East Greenland and South Africa, of the Hebridean volcanic centres of Skye and Rhum, and of Recent volcanic centres in the West Indies. The results of his extensive work on layered intrusions have formed the basis of a book almost completed at the time of his death, and due to be published this year (Wager and Brown, *Layered Igneous Rocks*). At Oxford, Wager was responsible for building up the facilities for petrographic, mineralogical and geochemical teaching and research which were to make it one of the better equipped centres in Britain. In addition, his period there saw an appreciable increase in the size of the whole department, including a new wing in 1964, and in the number of staff and students pursuing studies in most branches of geology.

Elected to a Fellowship of the Royal Society in 1946, he was also a Fellow of the Geological Society of London (vice-president, 1951–53), of the Royal Geographical Society, and of the Mineralogical Society of America; a member of the Mineralogical Society (president, 1960–63); and one-time president of Section C of the British Association for the Advancement of Science (1958). He served on several university, national, and international committees, and was a founder editor of *Geochimica et Cosmochimica Acta* and *Journal of Petrology*. He was awarded the Arctic Medal (1933); the Mungo Park Medal (1936); the Lyell Fund (1935), the Bigsby Medal (1945), and the Lyell Medal (1962) of the Geological Society of London; and the Spendiarov Prize at the eighteenth International Geological Congress in 1948.

Wager was an inspiring teacher and a born leader, his integrity and seriousness of purpose instilling in all who worked with him a deep sense of loyalty. He set high standards and was unstinting in his appreciation of those who tried to meet them, for he had a liberal mind and a generous heart. Staff and students could always depend on his valuable advice and would find him ready to spend any spare time he might have on discussing their technical or personal problems, however trivial. He had a rather retiring personality, was reluctant to talk of his exploits, and rarely displayed his deeper emotions. Yet his authority, drawn from a splendid association of courage, intellect, and gentle modesty, could never fail to impress, even in a casual encounter.

He is survived by his widow, who greatly helped him in his work, two sons and three daughters.

G. MALCOLM BROWN

Prof. W. F. Whittard

PROF. WALTER FREDERICK WHITTARD, professor of geology in the University of Bristol, died on March 2, at the age of 63.

Born in Clapham, London, on October 26, 1902, Whittard was educated at Battersea County Secondary School; he was a founder member of the school Natural History Club, and an early interest in geology was established by the finding of fossils in the Chalk near Purley. After a brief spell at the Chelsea Polytechnic, he proceeded to the Imperial College of Science and Technology to read geology under W. W. Watts. There he also studied zoology, so that Whittard's subsequent major interests in stratigraphy and palaeontology especially were determined early in his undergraduate days.

After obtaining his first degree, Whittard went to Shropshire at the instigation of Watts to study rocks of Llandovery age, and it was during this period that he developed a love for Shropshire and the Welsh Borderland which was to last the whole of his life. Following the award of the Ph.D. degree, Whittard went up to Sidney Sussex College, Cambridge. There he moved on to the study of Ordovician rocks, still in Shropshire, a critical area for a better understanding of the history of the Ordovician period.

In 1929, Whittard seized a chance opportunity to join the Cambridge East Greenland Expedition; he went as chief geologist, and carried out much useful work. This experience gave Whittard an enthusiasm for the Arctic regions which was later inherited by some of his students.

In 1931 he was appointed assistant lecturer in geology at the Imperial College of Science and Technology. As lecturer, Whittard remained there until 1937, when he was elected to the Chaning Wills chair of geology in the University of Bristol, lately vacated by Trueman. He

took over a department organized on traditional lines which accorded with his specialisms; despite this, with characteristic forward planning, Whittard began to adapt the department to the changes beginning to affect geology. This work was halted by the Second World War, but with the end of hostilities he resumed the modernization. It was during the difficult immediate post-war years that Whittard served the University well as dean of the Faculty of Science; both then and later he brought into play a sane and balanced judgment in the many University committees on which he served.

Whittard was elected a Fellow of the Royal Society in 1957. From 1952 to 1954 he had been president of the Bristol Naturalists' Society, and from 1961 to 1962 had served as vice-president of the Palaeontological Association. He was awarded the D.Sc. degree of the University of London, and in 1964 he became a Fellow of the Imperial College of Science and Technology. The last honour he was to receive was in 1965 when the Geological Society awarded him the Murchison Medal, and this brought considerable pleasure.

As a geologist, Whittard showed a wide diversity of interests which is borne out by the variety of his published works. Many papers dealt with the geology of Shropshire in which he had been actively engaged for nearly forty years. Whittard had accumulated an immense amount of detailed information on the geology of south Shropshire, and his field-maps were models of execution; it is a tragedy that he did not live to publish the geological map he had planned. Whittard wrote several papers on the geology of East Greenland, and on the Bristol district; he was joint editor of *Bristol and its Adjoining Counties* (1955).

In later years, after the completion of the Shropshire field-work, Whittard entered a fresh field of research. Excited by W. B. R. King's work on the geology of the floor of the English Channel, and with the co-operation of the director and staff of the Marine Biological Station, Plymouth, he threw himself with his usual energy into a systematic programme of coring and geophysical exploration of the Western Approaches. This work quickly produced important results, including the nature of marine sediments of Miocene and Pleistocene age, previously known nowhere in Britain. Through this research, the seventeenth Colston Symposium was devoted to "Submarine Geology and Geophysics", and the resulting publication was edited jointly by Whittard and his colleague, R. Bradshaw.

Whittard will be remembered above all for his painstaking work in palaeontology. He contributed to our knowledge of no less than five animal phyla, including the Amphibia, and he was an acknowledged expert on trilobites. For some years he had been engaged on the Palaeontographical Society's monograph, *Ordovician Trilobites of the Shelve Inlier, Western Shropshire*; at the time of his death the major part of this work had been published. It is a model of meticulously careful work, excellently illustrated, and the geological world is the poorer for the non-completion of a work in which Whittard's unique experience was of paramount importance.

Whittard was a man of quiet charm who enjoyed a happy home life. He found joy in his garden and especially in his collection of rock plants and alpines. At his home at Westbury-on-Trym he relaxed with music, reading and book-binding. He was keenly interested in the welfare of his students, and found gratification in having taken part in the training of so many young geologists.

Prof. Whittard is mourned by his wife and son. He will be missed acutely by his many friends and by geologists everywhere. His death is a grievous loss especially to British geology, and to the University of Bristol which he had served so loyally and well for almost thirty years.

F. WOLVERSON COPE

NEWS AND VIEWS

Royal Society of London

AT a meeting of the Royal Society on April 21, the following were elected foreign members of the Society: PROF. J. BRACHET, professor of animal genetics and biochemistry, Université Libre de Bruxelles, Brussels; PROF. H. K. HARTLINE, Rockefeller Institute, New York; PROF. L. E. F. NÉEL, professor of experimental physics, Université de Grenoble, Grenoble; PROF. A. WEIL, Institute for Advanced Study, Princeton, New Jersey.

U.S. National Academy of Sciences

THE following have been elected foreign associates of the National Academy of Sciences: PROF. H. ALFVÉN, professor of theoretical electrodynamics and mathematics, Royal Institute of Technology, Stockholm; PROF. P. M. S. BLACKETT, president, The Royal Society, London; SIR JOHN ECCLES, professor of physiology, Australian National University, Canberra; PROF. M. EIGEN, Max Planck Institute of Theoretical Chemistry, Gottingen; PROF. E. KATCHALSKI, Department of Biophysics, Weizmann Institute of Science, Rehovoth; PROF. K. LORENZ, director, Max Planck Institute for Behavioural Physiology, Bavaria; PROF. J. PIAGET, professor of psychology, University of Geneva; PROF. B. SANDER, professor emeritus of mineralogy and petrography, University of Innsbruck; PROF. P. SWINGS, director, Institute of Astrophysics, University of Liège; PROF. H. TAMIYA, Institute of Applied Microbiology, University of Tokyo.

Earth Sciences in the University of Leeds : Prof. E. Irving

DR. E. IRVING, senior scientific officer in the Division of Geomagnetism at the Dominion Observatory, Ottawa, has been appointed to a new chair of geophysics in the Department of Earth Sciences in the University of Leeds. He will take up the appointment in July. Dr. Irving was educated at Colne Grammar School, served in the Army from 1945 until 1948 and graduated at Cambridge in 1951. His research work, begun in Cambridge and continued after 1954 in the Australian National University, where he held a research fellowship and later a senior fellowship, has been largely devoted to the study of the magnetic properties of rocks and their application to problems in the earth sciences, in particular those relating to the theory of continental drift, and to such other problems as past climates and the distribution of oil. His recent book on palaeomagnetism is a comprehensive survey of this subject. At Leeds, where his work will fit well with that of the recently established geochronological unit under Dr. Dodson, and with the Research Institute of African Geology, he will develop research on geomagnetism and other geophysical methods which can help to solve some of the fundamental problems of the Earth.

Reactor Centrum Nederland

THE fifth summary of activities of Reactor Centrum Nederland, covering the period July 1, 1964–June 30,

1965, describes the development of a pressurized water reactor suitable for ship propulsion—the so-called NERO project. Part of this, carried out in association with Euratom, has been completed (Pp. 15. The Hague: Reactor Centrum Nederland, 1965). Work at Petten is concerned with the reactor core, consisting of sintered uranium oxide fuel in zircalloy tubes. The fuel contains discrete particles of burnable neutron poison, for which UB_4 and Dy_2O_3 are being considered. For testing, both the low-flux and the high-flux reactors have been used, and the effect of the introduction of poisoned fuel rods on the power distribution has been measured in the critical facility KRITO, using a two-zone core of 3·1 per cent and 3·8 per cent enrichment. The principal problem of the NERO design in the field of materials is the compatibility of the neutron poison particle with the fuel matrix, both during the fabrication of the fuel and during its life in the reactor.

The three reactors at Petten each play a part in the reactor development work and KRITO is used exclusively for that work. The 200-MW high-flux reactor is owned by Euratom as part of that organization's research establishment adjoining the RCN site but is operated by RCN. Two new loops and one new beamhole experiment have been installed. The experiment consists of a triple-axis spectrometer for the investigation of crystal lattice dynamics by the inelastic scattering of neutrons. Two other beamholes are in use for crystal structure studies by means of neutron diffraction. New information on the magnetic ordering in cobalt (II) oxide has been obtained. The 10-kW low-flux reactor has been made more versatile by the addition of a trolley in the large sub-critical facility which occupies one side of the reactor.

Rubbish in Estuaries

A STUDY by the U.K.A.E.A. Isotope Research Division has illustrated the difficulties of selecting areas for the deposition of spoil and sewage. The initial studies, carried out in 1961 and 1964 in the Firth of Forth, show that the Oxcars deep region, which has been used as an area for the deposition of spoil dredged from Rosyth dockyard, is totally unsuitable for the purpose. Far from being swept out to sea, the silt moves upstream, and is ultimately deposited near the region from which it was originally dredged.

The technique used in the experiments utilized radioactive tracers. Glass was prepared to the same density and size distribution as the silt, and scandium-46 was incorporated to enable the movement of the silt to be detected by scintillation counter. A hopper containing 750 tons of silt from Rosyth dockyard was inoculated thoroughly with tracer material and deposited in the normal way in Oxcars deep, immediately after slack high water. Within 24 hours, traces of silt were detected above the Forth Bridge, while below Oxcars deep no trace could be found. This pattern was maintained throughout the nine weeks in which measurements were made, despite the fact that deposition of the spoil was made at a state of the tide least likely to carry material upstream. Deposition of spoil is normally carried out at all states of the tide.

A subsequent study in 1965 of an area superficially less attractive for the dumping of silt has given different results. Although this area is shallower than the Oxcars deep, it is in an ebb channel, and the silt is swept out into the estuary.

Water in the United States

THE drought that has persisted in the eastern United States for the past few years, causing New York City to be classified as a 'disaster area', has emphasized that water supply can be as much a problem in industrial areas as in the farming areas of India and Africa. However, the problem for the United States should, with proper measures, be soluble. In a pamphlet for the United States Geological Survey, entitled *Has the United States Enough Water?*, A. M. Piper concludes that the United States can be assured of a sufficient water supply for essential needs within the near future if proper measures are taken soon. These include research before any decisions are made concerning management of water supplies; a realization that there is no one solution for all situations; compromise among potentially competitive uses; and large-scale investment for new water-management works.

Nearly all the fresh water comes from precipitation; rainfall in the United States varies from less than 4 in. per annum in the Pacific South-west to more than 85 in. in the Pacific North-west. This range of rainfall is complicated by an equally wide variation in potential 'evapotranspiration'—water loss from open-water surface and vegetable transpiration—ranging from 18 in. per annum in the Rocky Mountains to 60 in. in Death Valley. Where evapotranspiration exceeds precipitation, the land is arid; where precipitation is greater, water overflows into streams.

Where local needs are greater than the minimum stream-flow (which varies with the seasons), the variations must be suppressed, usually by means of reservoirs. At present the cost of controlling the water in a stream basin continuously has not been acceptable. However, Mr. Piper thinks that the acceptable cost will increase substantially and that the limitation on water storage will be determined by engineering complexities, other potential land uses, or other objectives of stream management.

In 1960, 270,000 million gallons of water were withdrawn each day from rivers in the United States, while 68,000 million gallons were actually consumed, 86 per cent in irrigation. At the present rate of increase, the total use of water will double in 25–30 years. When this increase is extrapolated forwards for each of sixteen regions in the United States, it appears that potential supply exceeds the likely commitment in only three regions; in another seven regions water requirements will be realized if virtually complete regulation of the stream-flow is feasible. In the remaining nine regions it is expected that even with complete regulation of stream-flow, social and industrial developments will be handicapped.

Lens Design at the N.B.S.

THE United States National Bureau of Standards has developed a procedure for the determination of lenses from design data alone, in response to a request from the Air Force Reconnaissance Laboratory at Wright Field and as an alternative to the expensive and time-consuming method of fabricating prototypes and then testing them. The system of optical design analysis is based on the use of spot diagrams, which are analogues of star image tests. In Monograph 93 of the National Bureau of Standards, O. R. Stavroudis and L. E. Sutton present an outline of the methods used to calculate, produce and interpret spot diagrams (United States Department of Commerce. *Spot Diagrams for the Prediction of Lens Performance from Design Data.* Pp. iii + 96. Washington, D.C.: Government Printing Office, 1965. 75 cents).

A spot diagram is a plot of points representing the intersections of rays from a given object point with a focal plane of a lens, and is calculated from the design specifications of the lens by the use of a fast digital computer. Within the framework of geometrical optics, the spot diagram can be interpreted in the same way as a star image produced by a real lens; it is the greatly magnified picture of the image of a point source as it would appear on the film plane of a camera using the lens. Hawkins and Linfoot in 1945 were the first to publish a report on spot diagrams when they described the performance of several designs of Schmidt cameras, and Herzberger, in 1947, followed with a report on the method of calculating the spot diagrams.

Since the introduction of fast digital computers, interest in spot diagrams has considerably increased. The computational procedures used to obtain the diagrams provide additional information about the lens, including data for estimating the resolving power, and information on vignetting, distortion and chromatic aberration.

The monograph emphasizes, however, that the spot diagram as a representation of the image of a point object is subject to certain limitations. Each ray is represented as contributing an equal amount to the intensity distribution of the image whereas, in reality, there is a considerable variation in the flux density associated with rays which travel along different paths through the lens. Moreover, each surface is entered at different angles of incidence, which means that different proportions of energy are transmitted. The intensity distribution in the dense portion of a spot diagram is likely to be underestimated, since the superimposition of one point of a spot diagram on another leads to only a single point. The diffraction effects due to the wave nature of light are not taken into account in the computation.

International Conference of Engineering Societies

At a meeting in Paris during April 13–15 representatives from the engineering federations—the Engineering Societies of Western Europe and the United States of America (E.U.S.E.C.), the Commonwealth Engineering Conference (C.E.C.), the Fédération Européenne d'Associations Nationales D'Ingenieurs (F.E.A.N.I.), and Union Panamericana de Asociaciones de Ingenieros (U.P.A.D.I.)—together with participants from Czechoslovakia, Hungary and the U.S.S.R., agreed on the need for a world organization of engineers. A proposed constitution for an International Conference of Engineering Societies was drawn up and will be submitted to the four organizations as soon as possible.

Eleanor Roosevelt International Cancer Fellowships

The International Union against Cancer, with the funds provided by the American Cancer Society, is to award fellowships for research on cancer. They will be awarded to persons on the staff of universities, teaching hospitals, research laboratories or similar institutions, and will be made to those investigating either the experimental or the clinical aspects of cancer. The fellowships will usually be awarded for one year, and applications must be received before September 1, for the period beginning March 1, 1967. Application forms and further information can be obtained from International Union against Cancer, P.O. Box 400, CH—1211, Geneva 2.

Gordon Research Conferences 1966

The Gordon Research Conferences, which are designed to stimulate research in universities, research foundations and industrial laboratories, will be held this year at five locations in New Hampshire and one in Washington during June 13–September 2. Sixty-six five-day conferences will be held, covering a wide range of topics in the physical and biological sciences. The purpose of the conferences is to discuss the most recent developments, analyse their significance, and provoke suggestions for future research. Further information and forms of application can be obtained from Dr. W. George Parks, Colby Junior College, New London, New Hampshire. Residence and registration charges for each conference will amount to 115 dollars.

Growth of University of Sussex

Lord Fulton, the Vice-Chancellor of the University of Sussex, who is retiring this summer, stresses in the sixth annual report of the University the rapid expansion in the 5 years since its foundation in 1961:

	1961–2	1962–3	1963–4	1964–5	1965–6
Academic faculty	9	63	117	197	
Students	55	442	898	1,504	2,090
Applications for admission		3,080	4,765	5,960	10,382

University News: Birmingham

Dr. P. J. Garner has been appointed to the newly established chair of chemical engineering. Dr. R. C. Curran has been appointed to the chair of pathology. The title of honorary professor in the Department of Electronic and Electrical Engineering has been conferred on Dr. E. V. D. Glazier, head of the Physics and Electronic Department at the Royal Radar Establishment. The title of honorary professor in the Department of Physics has been conferred on Dr. D. H. Parkinson, head of the Physics Group at the Royal Radar Establishment.

London

Dr. T. I. Shaw, principal scientific officer at the Plymouth Laboratory of the Marine Biological Association of the United Kingdom, has been appointed to the second chair of zoology, tenable at Queen Mary College. The title of reader in experimental haematology has been conferred on Dr. G. I. C. Ingram in respect of his post at St. Thomas's Hospital Medical School.

Dr. D. E. Barton, reader in statistics in University College, has been appointed to the chair of statistics tenable at Queen Mary College. The title of professor of virology has been conferred on Dr. L. H. Collier in respect of his post at the Lister Institute of Preventive Medicine.

Southampton

Dr. A. Carrington, assistant director of research in organic and inorganic chemistry, University of Cambridge, has been appointed to the fourth chair of chemistry as from October 1, 1967.

Appointments

Prof. R. L. Bisplinghoff, deputy head of the Department of Aeronautics and Astronautics in the Massachusetts Institute of Technology, has been appointed head of the Department as from July 1. He succeeds Prof. C. S. Draper, who will continue as a senior member of the faculty of the Department and as director of the Instrumentation Laboratory, which he founded more than 25 years ago.

Mr. G. C. Gaut, research director of the Plessey Co., Ltd., and Mr. A. Ross, chairman of the United Dominions Trust and a director of Eagle Star Insurance and of the Australia and New Zealand Bank, have been appointed part-time members of the National Research Development Corporation.

Mr. R. Eddison has been appointed managing director of Science in General Management, Ltd. (SIGMA), as from May 2. He succeeds Mr. Stafford Beer, who is joining the International Publishing Corporation, Ltd., as development director.

Announcements

Lord Hinton of Bankside has been elected the eighty-first president of the Institution of Mechanical Engineers, in succession to Mr. H. N. G. Allen.

A symposium on "Prostaglandins" will be held in Stockholm during June 6—8. Further information can be obtained from Dr. B. Samuelsson, Department of Chemistry, Karolinska Institutet, Stockholm 60.

The annual delegate conference of the Institution of Professional Civil Servants will be held in Hastings during May 23–25. Further information can be obtained from the General Secretary, Institution of Professional Civil Servants, Northumberland Street, London, W.C.2.

A symposium on "High Temperature Reactors and the *Dragon* Project", organized by the British Nuclear Energy

Society, will be held in London during May 23–24. Further information can be obtained from the Secretary, British Nuclear Energy Society, 1–7 Great George Street, Westminster, London, S.W.1.

AN open day will be held at the Agricultural Research Council Weed Research Organization on May 27. Further information can be obtained from B. A. Wright, A.R.C. Weed Research Organization, Begbroke Hill, Kidlington, Oxford.

A SYMPOSIUM on "Echinoderm Biology" will be held at the Zoological Society of London during May 25–26. Further information can be obtained from Prof. N. Millott, Zoology Department, Bedford College, Regent's Park, London, N.W.1.

AN ordinary meeting of the Scottish Section of the Society for Analytical Chemistry on "Thin-layer Chromatography" will be held in Paisley on May 31. Further information can be obtained from the Society for Analytical Chemistry, 14 Belgrave Square, London, S.W.1.

ERRATUM. In the article entitled "Thromboplastin-induced Hypercoagulability and its Prevention", by Dr. S. Nordstrom *et al.*, which appeared in the May 8, 1965, issue of *Nature*, the second sentence of paragraph one, p. 633, lines 5–8, should read: " 'Trasylol' has proved to be an antithromboplastin *in vitro*[3] and, more specifically, has been shown to block the reaction in which factors VIII, IX, X and contact factors take part[4]".

CORRESPONDENCE

Ships and String and Sealing-wax

SIR,—I have read your leader of April 9, 1966, with surprise, for I did not realize well-informed men could see things so differently.

You state: "prices are often uncompetitive and delivery dates too long". This paradox resolves itself. Prices are unremunerative, not uncompetitive, because in an attempt to keep labour forces from disintegrating, contracts have been accepted at too low a price. Further, for political reasons, foreign buyers have been subsidized by H.M. Government, berths are filled and booked for a long time and new deliveries can only be promised for distant dates. Rather than admit this, a shipbuilder required to tender may put forward a discouraging price. The position is aggravated by H.M. Government policy to coax new industries to shipbuilding areas where they compete for skilled labour, particularly in finishing trades. There is also the habit—of old standing—of making delivery promises for components which the maker has but a faint hope to honour.

You state: "Relationships between shipbuilders and the suppliers on whom they rely, particularly the engine makers, are too confused and complacent". However, so far as engines are concerned, the trouble is that half our shipbuilders, and probably all the major ones, build their own and that consequently production is fragmented instead of being concentrated into efficient units. There were, until recently, about nineteen British makers of marine steam turbines. Geddes implies there ought to be only one. I do not know the figures in regard to Diesels. Geddes says there ought to be four only.

The expenditure on research and development, I agree with you, is and has been far too low, but you cannot really relate it to total turnover, that is, the price of ships' hulls. Far too little was spent on steam installations, I agree, and what little was spent was frittered away by moving in all directions simultaneously, instead of being directed to improving economy of use by raising cycle efficiency and trustworthiness.

It is true that the heavy, slow Diesel "came into fashion" because it seemed, on paper, to be economically superior, but cycle efficiency of steam installations has improved to match Diesel efficiency, and steam turbine availability—days per year—has proved itself superior to that of Diesels. The fashion, therefore, will change again. Faster, medium-speed Diesels, I believe, will not be the solution. Not only is the efficiency inherently lower because of the unfavourable ratio of cylinder surface to volume, but also the incidence of failure increases with the number of components.

You speak approvingly of the recent powerful enhancement of the industry's concern for research and its availability to carry it out effectively. Presumably you are thinking of the re-organization of the British Ship Research Association in 1962. This, however, divorced design from 'research and development', and neither was subjected to the discipline arising from intimate connexion with producing, marketing and operating products. I do not know of any large-scale successful commercial undertaking working under such conditions. I therefore look forward to the implementation of the Geddes recommendations.

AN EXACT SOLUTION FOR DETERMINING MULTIPLE HIT FREQUENCIES IN FULLY CORRELATED FIRE

By E. V. GADECKI

Technical Operations, Incorporated, Burlington, Massachusetts

RECENTLY, Terry[1] outlined a mathematical construct for determining the probability of exactly m hits with n weapons when the distribution of shots is circular normal and centred at a point h units from the target origin. Terry proposes that the final integral for obtaining the unconditional probability that exactly m weapons will hit the target when n weapons are released can be evaluated numerically by employing the Laguerre–Gauss quadrature formula. In this article, an exact solution for this integral is provided in terms of a series.

Using the same notation as Terry, we shall proceed in a similar manner. The ballistic dispersion and aiming error are characterized by standard deviations σ_B and σ_A, respectively. The probability that a single weapon drawn at random strikes the target is given in polar coordinates as:

$$p=\int_0^R\int_0^{2\pi}\frac{1}{2\pi\sigma_B^2}r\exp\left[-\frac{1}{2\sigma_B^2}(r^2+h^2-2h\,r\,\cos\theta)\right]\mathrm{d}\theta\,\mathrm{d}r \qquad (1)$$

Rearranging terms in equation (1), we have:

$$p=\frac{1}{\sigma_B^2}\exp\left[-\frac{h^2}{2\sigma_B^2}\right]\int_0^R r\exp\left[-\frac{r^2}{2\sigma_B^2}\right]\left[\int_0^{2\pi}\frac{1}{2\pi}\exp\left[\frac{rh\cos\theta}{\sigma_B^2}\right]\mathrm{d}\theta\right]\mathrm{d}r \qquad (2)$$

The integral within the brackets can be expressed as a modified Bessel function:

$$\int_0^{2\pi}\frac{1}{2\pi}\exp\left[\frac{rh\cos\theta}{\sigma_B^2}\right]\mathrm{d}\theta=J_0\left[\frac{irh}{\sigma_B^2}\right]=I_0\left[\frac{rh}{\sigma_B^2}\right]$$

Accordingly, equation (2) can be rewritten as

$$p=\frac{1}{\sigma_B^2}\exp\left[-\frac{h^2}{2\sigma_B^2}\right]\int_0^R r\exp\left[-\frac{r^2}{2\sigma_B^2}\right]I_0\left[\frac{rh}{\sigma_B^2}\right]\mathrm{d}r \qquad (3)$$

Expanding $I_0\left[\frac{rh}{\sigma_B^2}\right]$ in its series form, we have:

$$I_0\left[\frac{rh}{\sigma_B^2}\right]=\sum_{k=0}^{\infty}\frac{1}{k!k!}\left(\frac{rh}{2\sigma_B^2}\right)^{2k}$$

Therefore,

$$p=\frac{1}{\sigma_B^2}\exp\left[-\frac{h^2}{2\sigma_B^2}\right]\int_0^R r\exp\left[-\frac{r^2}{2\sigma_B^2}\right]\sum_{k=0}^{\infty}\frac{1}{k!k!}\left(\frac{rh}{2\sigma_B^2}\right)^{2k}\mathrm{d}r$$

Since the series is obviously convergent after a finite number of terms, we can expand the series and integrate term by term. Using integration by parts and finite induction the following expression is arrived at:

$$p=\exp\left[-\frac{h^2}{2\sigma_B^2}\right]\sum_{i=0}^{\infty}\frac{\left(\frac{h^2}{2\sigma_B^2}\right)^i}{i!}\left[1-\exp\left[-\frac{R^2}{2\sigma_B^2}\right]\sum_{j=0}^{i}\frac{\left(\frac{R^2}{2\sigma_B^2}\right)^j}{j!}\right] \qquad (4)$$

Now the probability that m of n rounds will hit the target with aiming error, σ_A, is given by:

$$P_{[n,m]}=\int_0^{\infty}\frac{h}{\sigma_A^2}\exp\left[-\frac{h^2}{2\sigma_A^2}\right]\binom{n}{m}p^m(1-p)^{n-m}\,\mathrm{d}h \qquad (5)$$

If $m=n$, we have:

$$P_{[n,n]}=\int_0^{\infty}\frac{h}{\sigma_A^2}\exp\left[-\frac{h^2}{2\sigma_A^2}\right]p^n\,\mathrm{d}h \qquad (6)$$

or substituting equation (4) into equation (6), we have:

$$P_{[n,n]}=\int_0^{\infty}\frac{h}{\sigma_A^2}\exp\left[-\frac{h^2}{2\sigma_A^2}\right]\left\{\exp\left[-\frac{h^2}{2\sigma_B^2}\right]\sum_{i=0}^{\infty}\frac{\left(\frac{h^2}{2\sigma_B^2}\right)^i}{i!}\left[1-\exp\left[-\frac{R^2}{2\sigma_B^2}\right]\sum_{j=0}^{i}\frac{\left(\frac{R^2}{2\sigma_B^2}\right)^j}{j!}\right]\right\}^n\mathrm{d}h \qquad (7)$$

Now, since R and σ_B are constants in the expression:

$$1-\exp\left[-\frac{R^2}{2\sigma_B^2}\right]\sum_{j=0}^{i}\frac{\left(\frac{R^2}{2\sigma_B^2}\right)^j}{j!}$$

and only i is the variable, let us use G_i to represent this expression, that is:

$$G_i=1-\exp\left[-\frac{R^2}{2\sigma_B^2}\right]\sum_{j=0}^{i}\frac{\left(\frac{R^2}{2\sigma_B^2}\right)^j}{j!} \qquad (8)$$

Now using equation (8) in equation (7), we have:

$$P_{[n,n]}=\int_0^{\infty}\frac{h}{\sigma_A^2}\exp\left[-\frac{h^2}{2\sigma_A^2}\right]\left\{\exp\left[-\frac{h^2}{2\sigma_B^2}\right]\sum_{i=0}^{\infty}\frac{\left(\frac{h^2}{2\sigma_B^2}\right)^i}{i!}G_i\right\}^n\mathrm{d}h$$

$$=\int_0^{\infty}\frac{h}{\sigma_A^2}\exp\left[-\frac{h^2}{2\sigma_A^2}\right]\exp\left[-\frac{h^2n}{2\sigma_B^2}\right]\left\{\sum_{i=0}^{\infty}\frac{\left(\frac{h^2}{2\sigma_B^2}\right)^i}{i!}G_i\right\}^n\mathrm{d}h$$

$$=\int_0^{\infty}\frac{h}{\sigma_A^2}\exp\left[-h^2\left(\frac{\sigma_B^2+\sigma_A^2n}{2\sigma_A^2\sigma_B^2}\right)\right]\left\{\sum_{i=0}^{\infty}\frac{\left(\frac{h^2}{2\sigma_B^2}\right)^i}{i!}G_i\right\}^n\mathrm{d}h \qquad (9)$$

Let

$$v=h^2\left(\frac{\sigma_B^2+\sigma_A^2n}{2\sigma_A^2\sigma_B^2}\right)$$

Therefore:

$$\mathrm{d}v=h\left(\frac{\sigma_B^2+\sigma_A^2n}{\sigma_A^2\sigma_B^2}\right)\mathrm{d}h$$

$$\frac{\sigma_B^2\,\mathrm{d}v}{\sigma_B^2+\sigma_A^2n}=\frac{h}{\sigma_A^2}\,\mathrm{d}h$$

$$\frac{h^2}{2\sigma_B^2}=\frac{\sigma_A^2\,v}{\sigma_B^2+\sigma_A^2n}$$

Equation (9) becomes:

$$P_{[n,n]}=\frac{\sigma_B^2}{\sigma_B^2+\sigma_A^2 n}\int_0^\infty \exp(-v)\left\{\sum_{i=0}^{\infty}\frac{\left(\frac{\sigma_A^2 v}{\sigma_B^2+\sigma_A^2 n}\right)^i}{i!}G_i\right\}^n [dv$$

Let

$$C_n=\frac{\sigma_A^2}{\sigma_B^2+\sigma_A^2 n};\quad K_n=\frac{\sigma_B^2}{\sigma_B^2+\sigma_A^2 n}$$

Accordingly,

$$P_{[n,n]}=K_n\int_0^\infty \exp(-v)\left\{\sum_{i=0}^{\infty}\frac{(C_n v)^i}{i!}G_i\right\}^n dv \qquad (10)$$

Now the following two formulae are needed:

(I) $$\sum_{i=0}^{\infty}\frac{a_i x^i}{i!}\sum_{j=0}^{\infty}\frac{b_j x^j}{j!}=\sum_{k=0}^{\infty}\sum_{L=0}^{k}\binom{k}{L}a_L b_{k-L}\frac{x^k}{k!}$$

(II) $$\int_0^\infty e^{-x}\sum_{i=0}^{\infty}a_i\frac{(bx)^i}{i!}dx=\sum_{i=0}^{\infty}a_i b^i$$

Therefore, we have:

$$P_{[0,0]}=K_0\int_0^\infty \exp(-v)\,dv=K_0(1)=1$$

$$P_{[1,1]}=K_1\int_0^\infty \exp(-v)\sum_{i=u}^{\infty}\frac{(C_1 v)^i}{i!}G_i\,dv$$

Using formula (II):

$$=K_1\sum_{i=0}^{\infty}G_i C_1^i$$

$$P_{[2,2]}=K_2\int_0^\infty \exp(-v)\left\{\sum_{i=0}^{\infty}\frac{(C_2 v)^i}{i!}G_i\right\}^2 dv$$

Using formula (I):

$$=K_2\int_0^\infty \exp(-v)\left\{\sum_{i=0}^{\infty}\sum_{j=0}^{i}\binom{i}{j}G_j G_{i-j}\frac{(C_2 v)^i}{i!}\right\}dv$$

Using formula (II):

$$=K_2\sum_{i=0}^{\infty}\sum_{j=0}^{i}\binom{i}{j}G_j G_{i-j}C_2^i$$

Now set:

$$G_i^{(2)}=\sum_{j=0}^{i}\binom{i}{j}G_j G_{i-j}$$

And more generally:

$$G_j^{(t)}=\sum_{j=0}^{i}\binom{i}{j}G_j^{(t-1)}G_{i-j}\text{ where }t\geqslant 2$$

Therefore,

$$P_{[2,2]}=K_2\sum_{i=0}^{\infty}G_i^{(2)}C_2^i$$

Continuing this process and using finite induction, we find that:

$$P_{[n,n]}=K_n\sum_{i=0}^{\infty}G_i^{(n)}C_n^i\text{ for }n\geqslant 2 \qquad (11)$$

Now,

$$P_{[n,m]}=\binom{n}{m}\sum_{i=0}^{n-m}\binom{n-m}{i}(-1)^i P_{[m+i,m+i]} \qquad (12)$$

Equation (12) is derived by expanding equation (5) into a sum of integrals.

As a further simplification $P_{[1,1]}$ can be shown to be equal to:

$$1-\exp\left[-\frac{R^2}{2(\sigma_B^2+\sigma_B^2)}\right]$$

by expanding the series and terms within and then changing the order of addition.

As a summary of the results, then:

$$P_{[n,m]}=\binom{n}{m}\sum_{i=0}^{n-m}\binom{n-m}{i}(-1)^i P_{[m+i,m+i]}$$

where

$$P_{[0,0]}=1$$

$$P_{[1,1]}=1-\exp\left[-\frac{R^2}{2(\sigma_B^2+\sigma_A^2)}\right]$$

$$P_{[n,n]}=K_n\sum_{i=0}^{\infty}G_i^{(n)}C_n^i\text{ for }n\geqslant 2$$

where

$$K_n=\frac{\sigma_B^2}{\sigma_B^2+\sigma_A^2 n};\quad C_n=\frac{\sigma_A^2}{\sigma_B^2+\sigma_A^2 n}$$

$$G_i^{(n)}=\sum_{j=0}^{i}\binom{i}{j}G_j^{n-1}G_{i-j}\text{ for }n\geqslant 2$$

and

$$G_i=1-\exp\left(-\frac{R^2}{2\sigma_B^2}\right)\sum_{j=0}^{i}\frac{\left(\frac{R^2}{2\sigma_B^2}\right)^j}{j!}$$

I have written computer programmes to evaluate $P_{[n,m]}$ by this exact method, as well as by using the Laguerre–Gauss Quadrature Method with 2 abscissae and with 5 abscissae and, also by using the Gaussian Quadrature Method, with 14 abscissae while making the interval of integration finite. For comparison, I used the same input data into these four programmes. The radius, aiming error, and ballistic dispersion were all chosen to be 10 ft. and the number of rounds was 5. The results of the four programmes are given in Table 1.

Table 1

	Gauss (14 abscissae)	Laguerre–Gauss (2 abscissae)	Laguerre–Gauss (5 abscissae)	Exact
$P_{[s,0]}$	0·34446243	0·34454247	0·34455280	0·34455280
$P_{[s,1]}$	0·33457011	0·33539236	0·33538066	0·33538066
$P_{[s,2]}$	0·21411442	0·21302425	0·21301963	0·21301963
$P_{[s,3]}$	0·08546478	0·08554481	0·08554819	0·08554819
$P_{[s,4]}$	0·01942290	0·01955569	0·01956195	0·01956195
$P_{[s,5]}$	0·00193162	0·00193640	0·00193676	0·00193676

It was expected that the accuracy of the results should be better as Table 1 is read from left to right. The results tend to bear this out especially with the amazing correlation between the Laguerre–Gauss Quadrature Method with five abscissae and the exact method.

The comparison was inconclusive as to which method was faster. The programmes all had the same recorded time, which was also the minimum time the operators of the computer would record. It is my opinion that with an increase in the number of rounds the exact method would be shown to be faster.

DAMAGE PROBABILITIES IN FULLY CORRELATED FIRE

By Dr. E. R. TERRY

Technical Operations, Incorporated, Burlington, Massachusetts

I HAVE recently developed a construct for determining the probability of exactly m hits with n weapons when the distribution of shots is circular normal and is centred at a point h units from the origin of a circular target[1]. The construct could be used for determining the probability of exactly m damaging hits if the conditional damage function is assumed to be the circular 'cookie-cutter' function. For this damage function, the probability of damage with a single weapon is unity within some area about the weapon strike or burst point and is zero outside this area. More precisely, if the conditional damage probability to the target is $D(x, y)$ and the joint probability density function that describes the density of shots in the target plane is $f(x, y)$, then:

$$D(x, y) = \begin{cases} 1 & x^2+y^2 \leq R^2 \\ 0 & x^2+y^2 > R^2 \end{cases}$$

For this function, the probability of damage is:

$$p = \iint_{x^2+y^2 \leq R^2} f(x, y)\, dx dy$$

In this article, I shall develop a construct for determining the probability of multiple damaging hits for the same conditions outlined in my earlier work, except that the conditional damage function is assumed to be the circular Gaussian damage function first introduced by von Neumann[2]. For many situations, this is a more exact expression of the conditional damage function than the cookie-cutter function. Unlike the cookie-cutter function, as the radial distance from the strike or burst point increases, the damage probability gradually decreases from unity at the strike or burst point to zero. More precisely, for this situation we may write:

$$D(x, y) = \exp\left[-\frac{x^2+y^2}{a^2}\right] = \exp\left[-\left(\frac{r}{a}\right)^2\right]$$

where a is the equivalent damage radius. We note that:

$$\int_{-\infty}^{\infty}\int D(x, y)\, dx dy = \Pi\, a^2$$

As in my earlier investigation, I shall assume that the pattern of weapons is released on the target with a bivariate circular normal aiming error characterized by a standard deviation σ_A, and each weapon comprising the burst pattern is distributed about the mean point of impact or centroid of the pattern with a bivariate circular normal ballistic dispersion characterized by a standard deviation σ_B. I shall further assume that the ballistic dispersion for each of the weapons and the aiming error are mutually independent. Although a conditional damage probability is associated with each weapon comprising the burst pattern, no cumulative damage effect is assumed; that is, the probability of target damage is independent of the number of weapons striking the target.

Accordingly, the probability that a single weapon drawn at random will damage the target is given by:

$$p = \frac{1}{2\pi\sigma_B^2}\int_{-\infty}^{\infty}\int \exp\left\{-\frac{1}{2\sigma_B^2}\left[(x-h)^2+y^2\right]\right\} \exp\left[-\frac{x^2+y^2}{a^2}\right] dx dy$$

$$= \frac{1}{2\pi\sigma_B^2}\int_{\theta=0}^{2\pi}\int_{r=0}^{\infty} \exp\left[-\frac{1}{2\sigma_B^2}(r^2+h^2-2hr\cos\theta)\right] \exp\left[-\left(\frac{r}{a}\right)^2\right] r\, dr\, d\theta$$

$$= \frac{1}{2\pi\sigma_B^2}\int_{\theta=0}^{2\pi}\int_{r=0}^{\infty} \exp\left[-\frac{1}{2a^2\sigma_B^2}(a^2r^2+a^2h^2-2a^2hr\cos\theta+2\sigma_B^2r^2)\right] r\, dr\, d\theta \quad (1)$$

If we rearrange equation (1) thus:

$$p = \left\{\frac{1}{\sigma_B^2}\exp\left(-\frac{h^2}{2\sigma_B^2}\right)\int_{r=0}^{\infty} r\exp\left[-\left(\frac{a^2r^2+2\sigma_B^2r^2}{2a^2\sigma_B^2}\right)\right]\right\} \left[\frac{1}{2\pi}\int_{\theta=0}^{2\pi}\exp\left(\frac{hr\cos\theta}{\sigma_B^2}\right)d\theta\right] dr \quad (2)$$

we note that:

$$\frac{1}{2\pi}\int^{2\pi}\exp\left(\frac{hr\cos\theta}{\sigma_B^2}\right) = J_0\left(\frac{ihr}{\sigma_B^2}\right) = I_0\left(\frac{hr}{\sigma_B^2}\right)$$

which is the zero-ordered Bessel function of pure imaginary argument. Expanding $I_0(hr/\sigma_B^2)$ in its series form gives:

$$I_0\left(\frac{hr}{\sigma_B^2}\right) = \sum_{i=0}^{\infty}\frac{1}{(i!)^2}\left(\frac{hr}{2\sigma_B^2}\right)^{2i}$$

If we set:

$$u \equiv \frac{a^2r^2+2\sigma_B^2r^2}{2a^2\sigma_B^2}$$

and

$$du = \frac{a^2+2\sigma_B^2}{a^2\sigma_B^2}\, r\, dr$$

ADVANCED STUDY IN APPLIED MATHEMATICS LIBRARY

equation (2) can be put in the form:

$$p = \exp\left(-\frac{h^2}{2\sigma_B^2}\right)\left(\frac{a^2}{a^2+2\sigma_B^2}\right)\int_{u=0}^{\infty} \exp(-u)\, I_0\left(\frac{ha}{\sigma_B}\sqrt{\frac{2u}{a^2+2\sigma_B^2}}\right) du$$

$$= \exp\left(-\frac{h^2}{2\sigma_B^2}\right)\left(\frac{a^2}{a^2+2\sigma_B^2}\right)\sum_{i=0}^{\infty}\frac{1}{(2^i i!)^2} \int_{u=0}^{\infty}\left(\frac{ha}{\sigma_B}\sqrt{\frac{2u}{a^2+2\sigma_B^2}}\right)^{2i}\exp(-u)\, du \quad (3)$$

Noting that:

$$\int_0^{\infty}\frac{(Ku)^i e^{-u}}{i!}\, du = K^i$$

and putting equation (3) in the form:

$$p = \exp\left(-\frac{h^2}{2\sigma_B^2}\right)\left(\frac{a^2}{a^2+2\sigma_B^2}\right)\sum_{i=0}^{\infty}\frac{1}{2^{2i}i!} \int_{u=0}^{\infty}\frac{1}{i!}\left[\frac{2h^2a^2u}{\sigma_B^2(a^2+2\sigma_B^2)}\right]^i \exp(-u)du \quad (4)$$

$$p = \exp\left(-\frac{h^2}{2\sigma_B^2}\right)\left(\frac{a^2}{a^2+2\sigma_B^2}\right)\sum_{i=0}^{\infty}\frac{\left[\frac{h^2a^2}{2\sigma_B^2(a^2+2\sigma_B^2)}\right]^i}{i!}$$

we obtain

$$= \exp\left(-\frac{h^2}{2\sigma_B^2}\right)\left(\frac{a^2}{a^2+2\sigma_B^2}\right)\exp\left[\frac{h^2a^2}{2\sigma_B^2(a^2+2\sigma_B^2)}\right]$$

$$= \frac{a^2}{a^2+2\sigma_B^2}\exp\left[\frac{h^2a^2}{2\sigma_B^2(a^2+2\sigma_B^2)} - \frac{h^2}{2\sigma_B^2}\right]$$

$$= \frac{a^2}{a^2+2\sigma_B^2}\exp\left[-\frac{h^2}{a^2+2\sigma_B^2}\right] \quad (5)$$

Since the ballistic dispersions of all the weapons comprising the burst are independent of one another, the conditional probability of damaging the target with exactly m of n weapons is given by:

$$Q_{[n,m]} = \binom{n}{m} p^m (1-p)^{n-m} \quad (6)$$

and the probability density function for determining whether the mean point of impact is within an annulus of width dh at a distance h units in any direction from the centre of the target is given by:

$$dp_h = \frac{1}{\sigma_A^2}\exp\left(-\frac{h^2}{2\sigma_A^2}\right) h\, dh \quad (7)$$

Accordingly, the probability of exactly m of n weapons damaging the target is:

$$P_{[n,m]} = \frac{1}{\sigma_A^2}\int_{h=0}^{\infty}\exp\left(-\frac{h^2}{2\sigma_A^2}\right)\binom{n}{m}p^m(1-p)^{n-m}\, h\, dh \quad (8)$$

where p is given by equation (5).

Rearranging equation (8):

$$P_{[n,m]} = \frac{1}{\sigma_A^2}\binom{n}{m}\int_{h=0}^{\infty} h\exp\left(-\frac{h^2}{2\sigma_A^2}\right)p^m(1-p)^{n-m}\, dh \quad (9)$$

we can readily obtain a solution by expanding the binomial and integrating term by term. If n equals m, then the probability of exactly n of n weapons damaging the target is:

$$P_{[n,n]} = \frac{1}{\sigma_A^2}\int_{h=0}^{\infty} h\exp\left(-\frac{h^2}{2\sigma_A^2}\right)p^n\, dh$$

$$= \frac{1}{\sigma_A^2}\int_{h=0}^{\infty} h\exp\left(-\frac{h^2}{2\sigma_A^2}\right)\left[\frac{a^2}{a^2+2\sigma_B^2}\exp\left(-\frac{h^2}{a^2+2\sigma_B^2}\right)\right]^n dh \quad (10)$$

Setting

$$u \equiv \frac{h^2}{2\sigma_A^2}$$

$$du = \frac{h}{\sigma_A^2}\, dh$$

$$K \equiv \frac{2\sigma_A^2}{a^2+2\sigma_B^2}$$

and

$$W \equiv \frac{a^2}{a^2+2\sigma_B^2}$$

we can put equation (10) in the form:

$$P_{[n,n]} = \int_{u=0}^{\infty}\exp(-u)\left[W\exp(-Ku)\right]^n du$$

$$= W^n\int_{u=0}^{\infty}\exp(-u)\left[\exp(-Ku)\right]^n du$$

$$= W^n\int_{u=0}^{\infty}\exp(-u)\exp(-nKu)\, du$$

$$= W^n\int_{u=0}^{\infty}\exp\left[-u(nK+1)\right]du = \frac{W^n}{nK+1}$$

$$= \frac{a^{2n}}{(2n\sigma_A^2 + 2\sigma_B^2 + a^2)\,(a^2 + 2\sigma_B^2)^{n-1}} \qquad (11)$$

Accordingly, we then have:

$$P_{[0,0]} = 1$$

$$P_{[1,1]} = \frac{W}{K+1} = \frac{a^2}{2\sigma_A^2 + 2\sigma_B^2 + a^2}$$

$$P_{[2,2]} = \frac{W^2}{2K+1} = \frac{a^4}{(4\sigma_A^2 + 2\sigma_B^2 + a^2)\,(a^2 + 2\sigma_B^2)}$$

$$P_{[3,3]} = \frac{W^3}{3K+1} = \frac{a^6}{(6\sigma_A^2 + 2\sigma_B^2 + a^2)\,(a^2 + 2\sigma_B^2)^2}$$

$$\vdots$$

$$P_{[n+1,n+1]} = \frac{W^{n+1}}{(nK+K+1)} = \frac{a^{2(n+1)}}{(2(n+1)\sigma_A^2 + 2\sigma_B^2 + a^2)\,(a^2 + 2\sigma_B^2)^n}$$

The probability of exactly m of n damaging hits on the target for any m of n is:

$$P_{[n,m]} = \binom{n}{m} \sum_{i=0}^{n-m} (-1)^i \binom{n-m}{i} P_{[m+i,m+i]}$$

$$= \binom{n}{m} \sum_{i=0}^{n-m} (-1)^i \binom{n-m}{i} \frac{W^{m+i}}{mK + iK + 1} \qquad (12)$$

where from above:

$$W = \frac{a^2}{a^2 + 2\sigma_B^2} \qquad (13)$$

and

$$K = \frac{2\sigma_A^2}{a^2 + 2\sigma_B^2} \qquad (14)$$

Comparing the results given here with those of my earlier investigation, we see that the circular Gaussian damage function not only provides a more realistic description of the conditional damage function for certain situations, but also facilitates obtaining the integrals and implifying the resulting expressions[3]. From the point of view of target damage assessments, however, since a considerable number of variables must be considered, it is evident that a conditional damage function that accurately describes the effects of these variables will be far more complex than either the cookie-cutter or Gaussian damage functions.

For some weapon terminal effects, the conditional damage function appears to lie somewhere between these two functions. A sequence of functions of this type has been proposed by Dobbie[4]. The first member of the sequence is the Gaussian damage function and the limiting member is the 'cookie-cutter' damage function. It has the property that the probability integrals for most situations can be computed in finite form in terms of known functions. The second member of the sequence yields probabilities that lie approximately half-way between the corresponding probabilities for the Gaussian and 'cookie-cutter' damage functions. This property can be used to approximate the difficult cases arising out of using the 'cookie-cutter' function. Since the second member of the sequence is generally a better description of the conditional damage function than the 'cookie-cutter' function, it would appear to be more feasible to use the probabilities provided by this second member of the sequence.

Our assumption apropos of cumulative damage effects is questionable, since we would normally expect more damage from several weapons striking the target than from a single weapon. The problem here is not one of mathematics but of a paucity of data on the vulnerability of targets subjected to multiple hits. From the viewpoint of operational effectiveness, however, several questions arise. If the situation is such that a single hit is insufficient to destroy a target, then an attempt should be made to make the ballistic dispersion negligible in comparison to the aiming error. If the resulting pattern is too small, however, either all weapons will strike the target or none. It can be argued of course that if a single weapon strikes a vulnerable component of the target and does not damage it, then a larger calibre weapon or different fusing is required. If, on the other hand, only one hit is sufficient to damage the target, then the ballistic dispersion should be increased. As the resulting pattern is enlarged, the probability of at least one hit approaches a maximum representing the optimum pattern[5].

Addendum. The solution to equation (1) can be obtained more readily by separating the basic integral accordingly:

$$p = \frac{1}{2\pi\sigma_B^2} \int_{-\infty}^{\infty} \exp\left\{-\left[\frac{(x-h)^2}{2\sigma_B^2} + \frac{x^2}{a^2}\right]\right\} dx \int_{-\infty}^{\infty} \exp\left\{-\left[\frac{y^2}{2\sigma_B^2} + \frac{y^2}{a^2}\right]\right\} dy$$

The first integral can be written:

$$\int_{-\infty}^{\infty} \exp\left(-\frac{x^2}{2\sigma_B^2} + \frac{xh}{\sigma_B^2} - \frac{h^2}{2\sigma_B^2} - \frac{x^2}{a^2}\right) dx = \exp\left(-\frac{h^2}{2\sigma_B^2}\right) \int_{-\infty}^{\infty} \exp\left[-\left(\frac{1}{2\sigma_B^2} + \frac{1}{a^2}\right)x^2 + \frac{xh}{\sigma_B^2}\right]$$

We note that

$$\int_{-\infty}^{\infty} \exp\,(-ax^2 + bx)\,dx = \frac{1}{\sqrt{a}} \exp\left(\frac{b^2}{4a}\right) \int_{-\infty}^{\infty} \exp\,(-y^2)\,dy = \sqrt{\frac{\pi}{a}} \exp\left(\frac{b^2}{4a}\right)$$

This together with the corresponding expression for y reduces equation (1) to

$$p = \frac{a^2}{a^2 + 2\sigma_B^2} \exp\left[-\frac{h^2}{a^2 + 2\sigma_B^2}\right]$$

EFFECTIVENESS OF PATTERNS OR GROUPS OF WEAPONS RELEASED WITH A SINGLE AIMPOINT IN THE PRESENCE OF ZERO BALLISTIC DISPERSION

By DR. E. R. TERRY and E. V. GADECKI
Technical Operations Research, Burlington, Massachusetts

IT has been shown that if a pattern or group of weapons released with a single aimpoint is absolutely 'rigid', each weapon in the pattern will impact at its intended aimpoint and only two parameters—the number of weapons in the pattern and the spacing between weapons —are required to define the pattern[1]. Such a condition would arise if the patterns were released in the absence of ballistic dispersion. Admittedly, dispersionless patterns never exist in reality. Our interest in investigating these patterns was solely to provide one of several checks on the logic of the previously reported computer programmes[1-4]. However, our equations can be used satisfactorily as approximations when the ballistic dispersion is small.

When a pattern of weapons is released in a salvo in which there is zero spacing between weapons, if the conditional damage function is the circular 'cookie-cutter' function[2], the presence of zero ballistic dispersion will result in the probability of no less than a specified number of damaging hits being independent of the number of weapons in the pattern and equal to the probability of damaging the target with a single weapon drawn at random. The probability of exactly m of n damaging hits on a circular target of radius R when the conditional damage function is the circular 'cookie-cutter' function and the distribution of shots is circular normal and centred at a point h units from the target origin can be determined from:

$$P_{[n,m]}=\frac{1}{\sigma_A^2}\int_{h=0}^{\infty}\exp\left(-\frac{h^2}{2\sigma_A^2}\right)p^m(1-p)^{n-m}\,h\,dh\ (0\leqslant p\leqslant 1) \quad (1)$$

where:

$$p=\frac{1}{\sigma_B^2}\exp\left(-\frac{h^2}{2\sigma_B^2}\right)\int_{r=0}^{R}\exp\left(-\frac{r^2}{2\sigma_B^2}\right)I_0\left(\frac{rh}{\sigma_B^2}\right)r\,dr$$

$$=\exp\left(-\frac{h^2}{2\sigma_B^2}\right)\sum_{i=0}^{\infty}\frac{\left(\frac{h}{2\sigma_B^2}\right)^i}{i!}\left[1-\exp\left(-\frac{R^2}{2\sigma_B^2}\right)\sum_{j=0}^{i}\frac{\left(\frac{R^2}{2\sigma_B^2}\right)^j}{j!}\right] \quad (2)$$

$I_0(x)$ is the zero-ordered Bessel function of pure imaginary argument, and σ_A and σ_B are the aiming error standard deviation and ballistic dispersion, respectively[3,4]. When $\sigma_B=0$, we have

$$p=\begin{cases}1, & \text{when } h<R\\ 0, & \text{when } h>R\end{cases} \quad (3)$$

Accordingly, rewriting equation (1):

$$P_{[n,m]}=\frac{1}{\sigma_A^2}\int_{h=0}^{\infty}\exp\left(-\frac{h^2}{2\sigma_B^2}\right)p^m(1-p)^{n-m}\,h\,dh$$

$$+\frac{1}{\sigma_A^2}\int_{h=R}^{\infty}\exp\left(-\frac{h^2}{2\sigma_A^2}\right)p^m(1-p)^{n-m}\,h\,dh \quad (4)$$

if we set $m=n$ and replace the variable of integration by a function of a new variable, we obtain:

$$P_{[n,n]}=\int_{u=0}^{R^2/2\sigma_A^2}e^{-u}\,du=1-\exp\left(-\frac{R^2}{2\sigma_A^2}\right)=P_{[1,1]} \quad (5)$$

Similarly, if we set $m=0$, we obtain:

$$P_{[n,0]}=\int_{u=R^2/2\sigma_A^2}^{\infty}e^{-u}\,du=\exp\left(-\frac{R^2}{2\sigma_A^2}\right)$$

$$=P_{[1,0]}=1-P_{[1,1]} \quad (6)$$

so that $P_{[n,0]}=1-P_{[n,n]}$. By inspection of equation (4) we see that for all values of m such that $0<m<n$, $P_{[n,m]}=0$. Accordingly, since the probability of at least m of n damaging hits, say $P_{n,m}$, can be obtained from the following relationship:

$$P_{n,m}=1-P_{[n,0]}-P_{[n,1]}-P_{[n,2]}-\cdots-P_{[n,m-1]}$$

$$=1-\sum_{i=0}^{m-1}P_{[n,i]}=\sum_{i=m}^{n}P_{[n,i]} \quad (7)$$

we may write:

$$P_{n,m}=P_{[n,n]}=1-\exp\left(-\frac{R^2}{2\sigma_A^2}\right),\ (\sigma_B=0) \quad (8)$$

If we assume now that the conditional damage function is the circular Gaussian damage function[2], the probability of damaging the target with exactly m of n weapons is given by:

$$P_{[n,m]}=\binom{n}{m}\sum_{i=0}^{n-m}(-1)^i\binom{n-m}{i}\frac{W^{m+i}}{mK+iK+1},\ (n\geqslant m) \quad (9)$$

where

$$W=\frac{a^2}{a^2+2\sigma_B^2} \quad (10)$$

$$K=\frac{2\sigma_A^2}{a^2+2\sigma_B^2} \quad (11)$$

a is the equivalent damage radius, and the probability of damaging the target with a single weapon drawn at random is given by:

$$p=\frac{a^2}{a^2+2\sigma_B^2}\exp\left(-\frac{h^2}{a^2+2\sigma_B^2}\right) \quad (12)$$

When $\sigma_B=0$, W is unity, $K=2\sigma_A^2/a^2$, and equation (9) reduces to:

$$P_{[n,m]}=\binom{n}{m}\sum_{i=0}^{n-m}(-1)^i\binom{n-m}{i}\frac{a^2}{2\sigma_A^2(m+i)+a^2},$$

$$(n\geqslant m,\ \sigma_B=0) \quad (13)$$

For this damage function the probability of at least m of n damaging hits is not equal to the probability of damaging the target with a single weapon drawn at random (given by equation (12)), since this latter probability, irrespective of the aiming error, always assumes some finite value between zero and unity, that is, $p\neq 0$.

If a pattern is released with a certain non-zero spacing between weapons, then whether or not a weapon in the pattern damages the target will depend on the pattern reference point (whose aimpoint is the aimpoint for the pattern as a whole) and the distance its aimpoint is offset from the pattern reference point. We shall illustrate this with an example drawn from stick (train) bombing[1,5,6]. Consider a vulnerable infinite-line or strip target of width $2W$ so located that the centreline of the target is coincident with the x axis. An aircraft approaches the target on a perpendicular course and releases a linear pattern of n weapons, aiming the centre weapon at the centre of the target with linear spacing Δy_i. To simplify the problem, it is assumed that n is an odd integer and that the linear spacing between weapons is less than the target width. Damage obtains from a hit with the ith weapon in the pattern if it impacts in the target plane at a point y_i such that:

$$p_i = \begin{cases} 1, \text{ if } -W \leqslant y_i \leqslant W \\ 0, \text{ otherwise} \end{cases} \qquad (14)$$

If the aimpoints of the individual weapons in the pattern are defined in relation to the aimpoint of some reference point in the pattern, say $\bar{y}_A$, and the pattern aimpoint is the aimpoint of the reference point (the centre weapon, for our example), then the probability of at least m of n damaging hits with a pattern of n weapons is given by:

$$P_{n,m} = \int_{-\infty}^{\infty} f_A(\eta)\, Q_{n,m}\, d\eta \qquad (15)$$

where

$$f_A(\eta) = \frac{1}{\sqrt{2\pi}\,\sigma_A} \exp\left\{-\frac{1}{2}\left[\left(\frac{\eta-\bar{y}_A}{\sigma_A}\right)^2\right]\right\} d\eta \qquad (16)$$

$$Q_{n,m} = \sum_{j=m}^{n} (-1)^{j-m} \binom{j-1}{m-1} S_j^{(n)}, \quad (m = 1, 2, \ldots, n) \qquad (17)$$

$$S_1^{(n)} = \sum_j p_{ij}, \; S_2^{(n)} = \sum_{j<k} p_{ij}\, p_{ik}, \ldots,$$

$$S_n^{(n)} = p_{i1}\, p_{i2} \cdots p_{in} \qquad (18)$$

$$p_i(\eta) = \frac{1}{\sqrt{2\pi}\,\sigma_B} \int_{-W}^{W} \exp\left\{-\frac{1}{2}\left[\left(\frac{y-\bar{y}_i}{\sigma_B}\right)^2\right]\right\} dy_i$$

$$= \operatorname{erf}\left(\frac{W-\bar{y}_i}{\sigma_B\sqrt{2}}\right) \operatorname{erf}\left(\frac{W+\bar{y}_i}{\sigma_B\sqrt{2}}\right) \qquad (19)$$

$\bar{y}_i$ is the mean point of impact of the ith weapon where:

$$\bar{y}_i = \eta + \Delta y_i \qquad (20)$$

and $d\eta$ and dy_i are the error and target co-ordinate systems similarly oriented with origins at the target centre and the pattern reference point, respectively. Here $f_A(\eta)$ is the aiming error probability density function for determining whether the pattern reference point is placed between η and $\eta + d\eta$. The $Q_{n,m}$ and $p_i(\eta)$ are conditional probabilities of obtaining at least m of n damaging hits with a pattern of n weapons and of obtaining a damaging hit with the ith weapon in the pattern, respectively, given that the aiming error is placed at η.

If $\sigma_B = 0$ and we assume for the moment that all the p_i are equal (that is, that the weapons in the pattern are released with zero spacing), then damaging hits obtain only under the conditions expressed by equation (14). Thus, for this situation the pattern reference point, $\bar{y}_A$, must be placed such that $-W \leqslant y_A \leqslant W$. The probability that the pattern reference point is so placed, which is also the probability that at least m of n weapons damage the target, is given by:

$$P_{n,m} = \frac{1}{\sqrt{2\pi}\sigma_A} \int_{-W}^{W} \exp\left[-\frac{1}{2}\left(\frac{\bar{y}_A}{\sigma_A}\right)^2\right] dy$$

$$= \operatorname{erf}\left(\frac{W}{\sigma_A\sqrt{2}}\right) \qquad (21)$$

Now let us assume that the weapons are released with a specified non-zero spacing. To determine the probability of no less than a specified number of damaging hits, we must first determine the maximum number of hits possible, taking into consideration the target width and pattern length, l. The latter is equal to the product $(n-1)\Delta y_i$. If the pattern reference point (that is, the centre weapon in the pattern) misses the target centre by a distance greater than $(2W+l)/2$, none of the weapons will damage the target. Conversely, if the pattern reference point is placed a distance less than $(2W+l)/2$ from the target centre, damaging hits will obtain. Thus, if the pattern reference point is placed in a central strip of width $2W+l$, at least one weapon damages the target and the probability that the pattern reference point is so placed is:

$$P_{n,1} = \frac{1}{\sqrt{2\pi}\,\sigma_A} \int_{-(2W-l)2}^{(2W+l)/2} \exp\left[-\frac{1}{2}\left(\frac{\bar{y}_A}{\sigma_A}\right)^2\right] dy$$

$$= \operatorname{erf}\left(\frac{2W+l}{\sigma_A\, 2\sqrt{2}}\right) \qquad (22)$$

Similarly, if the pattern reference point is placed in a central strip of width $2W+l-2\Delta y_i$, at least two weapons will damage the target, and the probability that the pattern reference point is so placed is:

$$P_{n,2} = \frac{1}{\sqrt{2\pi}\,\sigma_A} \int_{-(2W-l-2\Delta y_i)/2}^{(2W+l-2\Delta y_i)/2} \exp\left[-\frac{1}{2}\left(\frac{\bar{y}_A}{\sigma_A}\right)^2\right] dy$$

$$= \operatorname{erf}\left(\frac{2W+l-2\Delta y_i}{\sigma_A\, 2\sqrt{2}}\right) \qquad (23)$$

For the general case, we can show in a similar manner that, if the pattern reference point is placed in a central strip of width $2W+l-2\Delta y_i(r-1)$, at least m damaging hits obtain, and the probability that the pattern reference point is so placed is:

$$P_{n,m} = \frac{1}{\sqrt{2\pi}\,\sigma_A} \int_{-[2W+l-2\Delta y_i(m-1)]/2}^{[2W+l-2\Delta y_i(m-1)]/2} \exp\left[-\frac{1}{2}\left(\frac{\bar{y}_A}{\sigma_A}\right)^2\right] dy$$

$$= \operatorname{erf}\left[\frac{2W+l-2\Delta y_i(m-1)}{\sigma_A\, 2\sqrt{2}}\right] \qquad (24)$$

It is our belief that had these findings been generally appreciated in the past, damage probability curves in previously published works on the phenomenology of releasing weapon patterns with a single aimpoint might have been drawn somewhat differently.

A DIGITAL COMPUTER ANALYSIS OF PALAEOLITHIC FLINT ASSEMBLAGES

By J. E. DORAN
Experimental Programming Unit, University of Edinburgh
AND
DR. F. R. HODSON
Institute of Archaeology, University of London

BORDES'S numerical methods of describing and classifying complex assemblages of flint artefacts have provided a new approach to Palaeolithic studies. These methods describe assemblages by the percentage of occurrence of a fixed range of types and classify them on this basis[1]. However, the presentation and analysis of this kind of data are by no means straightforward and it has proved difficult to compare comprehensively more than a few assemblages together, and also to make use of the full range of data in classification. This article describes experiments with one possible aid to the study of these and similar kinds of data.

A multi-dimensional scaling procedure developed by Shepard[2] and Kruskal[3] primarily for use in psychological research has been applied to archaeological material. The method operates on a set of 'units', in this case flint assemblages, any two of which are related by a numerical 'similarity coefficient'. It arranges points, each corresponding to a unit, in a prescribed number of dimensions so that the distances between the points reflect the magnitudes of the corresponding similarities. Configurations of points in one or two dimensions form 'maps' which are convenient to study, and which may reveal structure inherent in the data.

Full details of the procedure are given elsewhere[4]. Briefly, a digital computer is programmed (our programme is written in Algol) to generate a random configuration of points in a prescribed number of dimensions and then iteratively to rearrange the points until a configuration which best fits the data is obtained. For any configuration a measure of goodness of fit may be calculated which we call the 'strain' (Shepard's 'delta'). That configuration with the least strain is the most valuable. Normally, when an optimal two-dimensional configuration has been achieved, it is then collapsed into one dimension and used to initiate a search for the best linear arrangement of the points.

The application of this method to archaeological material has been tested most fully so far on a series of thirty Iron Age brooches which could be described numerically by the presence and absence of various features. In these tests[4], the analysis produced configurations which were consistent with a rough chronology deduced from independent evidence. Its performance also compared favourably with a series of 'intuitive' analyses carried out on the same material by a group of professional archaeologists.

For the experimental analysis of Palaeolithic material to be described here, sixteen assemblages were chosen from a wide range of well-documented sites of the Mousterian culture—the culture regularly associated with Neanderthal remains. A number of stratified assemblages were included since their known chronological ordering would help in assessing the value of the computed results.

The data, all taken from authors who used Bordes's list of categories, were used in two forms. The first was Bordes's 'essential' form which excludes some retouched flakes of dubious significance (for example, some that may have been 'retouched' by natural agencies). These essential data have been modified slightly for the present analysis to exclude Bordes's miscellaneous category 62 ('divers') and to include 'bifaces' as an additional single category within the list of types. The second form of data used was Bordes's 'real' data, which included all retouched flakes.

A similarity coefficient S_{ij} was calculated for each pair (i,j) of assemblages according to the formula:

$$S_{ij} = \sum_{t=1}^{n} (P_{it}\, P_{jt})^{\frac{1}{2}}$$

where the summation is over the n types, and where P_{it} is the percentage of flakes of assemblage i which is of type t. The formula takes the square roots of the percentages to improve the characteristics of the coefficient.

Repeated analyses from different random starting configurations were carried out, and low-strain configurations were produced in two dimensions for both the essential and the real data, but in one dimension for the essential data only. This implies that the real data were not consistent with a linear arrangement of the assemblages. Successive low-strain configurations from the same data varied within only narrow limits. Typical configurations are illustrated in Figs. 1 and 2.

For the essential data, which are perhaps theoretically more reliable, the two-dimensional configuration suggests

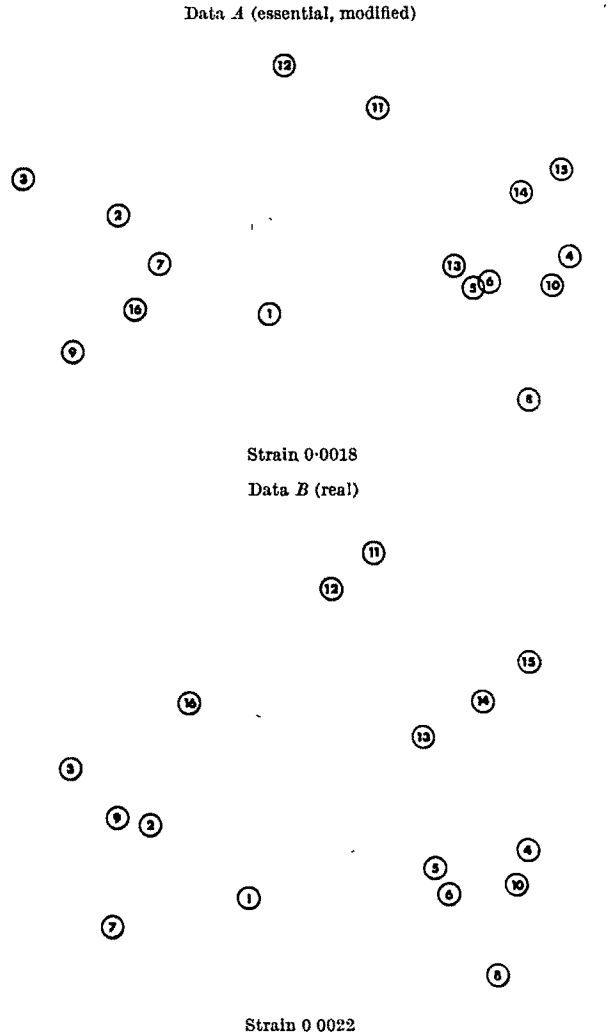

Fig. 1. Computed two-dimensional configurations of sixteen Mousterian assemblages: (1)–(3) Pech d'Azé (Dordogne) levels 4, *B*, 7 (ref. 8), (4)–(7) Chadourne (Dordogne) levels *D*, *C*, *B*, *A* (ref. 9); (8)–(9) Haute-Roche (Charente), lower and middle levels (ref. 10); (10) l'Ermitage (Vienne) (ref. 11); (11) Oissel (Seine-Inf.) (ref. 12), (12) Houppeville (Seine-Inf.), série claire (ref. 12); (13) Rigabe (Var) level *G* (ref. 13); (14) Prince (Grimaldi) foyer *E* (ref. 14); (15) Kokkinopulos (Greece), surface finds (ref. 15); (16) Romani (Barcelona), levels 9/9*a*/9*b* (ref. 16)

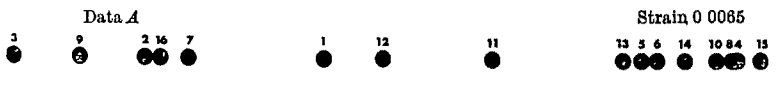

Fig. 2. Computed one-dimensional configuration of sixteen Mousterian assemblages from modified 'essential' data. 'Real' data refused to yield a low strain configuration in one dimension

two principal clusters of points around the ends of a main axis (I to the right, II to the left) with two assemblages, 11 and 12, apart, perhaps suggesting a third focus (III) roughly equidistant from I and II.

The arrangement of the stratified assemblages is consistently with earlier assemblages to the right of later (1–2–3; 4–6/5—7; 8–9). Assemblages 5 and 6, which apparently form an exception, have been shown by Vértes not to differ significantly in their content although they are from different levels in the Abri Chadourne[6]. Assemblages 11 (Oissel at the base of Loess récent I) and 12 (Houppeville at the base of Loess récent II), which may be dated relatively by their geological position, conform to the general pattern.

The same consistent placing of stratified assemblages is found in the one-dimensional configuration.

The two-dimensional configuration obtained from the real data reproduces the main features just described. However, assemblages 13, 14 and 15 are here separated from the main cluster I, and the relative position of some single assemblages within the other main group II varies considerably. These differences between the configurations derived from the essential and the real data were obtained consistently.

It would be unwise to draw general conclusions from the analysis of so few assemblages as this. However, it may be noted that the three main clusters which suggest themselves in the two-dimensional configurations correspond broadly, though not completely, with the main divisions of the Mousterian which Bordes suggests (largely on the evidence of discontinuity in the frequency distribution of racloirs). Group 1, to the right of the diagram, corresponds with Bordes's Charentian, and group III (assemblages 11 and 12) with his typical Mousterian. However, group II includes assemblages variously classified by Bordes as Denticulate Mousterian (7 and 9), and as Mousterian of Acheulian tradition types *A* and *B* (assemblages 1 as type *A*, 2 and 3 as type *B*). It is interesting that for both sets of data the scaling analysis, which is effectively 'polythetic' in Sneath's[6] terms, relates the important assemblage 1 to other assemblages from the Dordogne (to 2, a higher level in the same cave, and to 7) rather than to assemblages from the Seine basin (11 and 12). This is despite a racloir index which would certainly group 1 with 11 and 12 were a monothetic system of classification based on the racloir frequency followed.

The assemblages separated from our group I by the real data, but not by the essential data, are from south-easterly sites and include 15, the patinated series of surface flints from Kokkinopilos, Greece.

The placing of assemblage 1, and the seemingly strong correlation between typological development and chronology which is implied by the positioning of the stratified assemblages perhaps lend support to Mellars's view[7] that typological differences between some of the main Mousterian groups may have more chronological significance than Bordes himself admits.

From our preliminary work we are encouraged to believe that this method of analysis provides a convenient and objective means of presenting archaeological data which it is otherwise difficult to study. It is likely to reveal clustering and trends within the material and so to aid classification and interpretation. In the analysis described here, it seems that the main axis of the two-dimensional configurations may well correspond with time, and in addition definite clusters are indicated which emphasize variation in a second dimension around this main axis. Thus multidimensional scaling provides a kind of improved seriation of the material, avoiding many of the limitations inherent with normal seriation techniques. An optimal one-dimensional configuration produces seriation with relative spacing of points as well as ordering, and is accompanied by a numerical measure of the distortion involved in obtaining a linear representation of the data. An optimal two-dimensional configuration is distorted only to the extent that the data require three or more dimensions for their accurate representation, and again this distortion is measured. Without safeguards of this nature, seriation is liable to assume linearity where none exists.

We plan to use these methods to analyse a more complete series of relevant Palaeolithic assemblages.

We thank Prof. D. G. Kendall of the University of Cambridge and Dr. J. B. Kruskal for valuable advice, and the staff of the London University Computer Unit for much assistance. The programme used for this work was developed for general purposes at the Unit of Biometry, University of Oxford, and the Experimental Programming Unit, University of Edinburgh, under the aegis of Dr. N. T. J. Bailey and Dr. D. Michie, respectively.

OCCURRENCE OF COMPOSITIONALLY ZONED ALMANDITIC GARNETS IN REGIONALLY METAMORPHOSED ROCKS

By B. HARTE* and K. J. HENLEY†

Department of Mineralogy and Petrology, Cambridge, and Department of Geology, University College, London

ALMANDITIC garnets have received much attention from metamorphic petrologists for a variety of reasons, including: (1) the use of almandite as an isograd mineral in regional metamorphic sequences; (2) the possible relation of garnet composition to host-rock composition, metamorphic grade, and the partitioning of elements between co-existing phases[1–4]; (3) the use of the internal textures of garnets in investigating phases of garnet growth (that is, metamorphism) in relation to phases of deformation[5–6]; and (4) the use of garnet in

* Present address: Grant Institute of Geology, Edinburgh.
† Present address: Warren Spring Laboratory, Stevenage, Hertfordshire.

studying nucleation and growth of metamorphic minerals[7]. As a result of such studies, a reasonable amount of data on the chemical composition of almanditic garnets in regional metamorphic terrains has accumulated, but few investigations have been made of the variation in chemical composition of garnets within a single microscope slide, both from the point of view of estimating the attainment of chemical equilibrium, and also in evaluating the relation of any chemical variation to the internal textural variation. From this and other points of view, we have recently investigated a number of metamorphic minerals from two regional metamorphic terrains using the electron-probe microanalyser in the Department of Mineralogy and Petrology, University of Cambridge, and a brief summary of the results on almanditic garnets is presented here.

The rocks investigated come from two distinct regions, the Glen Esk area in the south-east Grampian Highlands of Scotland (B. H.), and the Sulitjelma region, North Norway (K. J. H.). The rocks studied from the Glen Esk area are pelites, with the typical mineral assemblage: quartz, plagioclase, muscovite, biotite, garnet, staurolite, ±kyanite, ±sillimanite, and come from the staurolite, kyanite and sillimanite zones of Barrow[8]. The garnets in these rocks commonly show straight or slightly sigmoidal inclusion trails (S_i) of fine-grained quartz and iron ore. The material studied from Sulitjelma ranges in grade from the biotite to the kyanite zone, and consists of pelites and calcareous pelites of the following mineral assemblages: (1) quartz, biotite, muscovite, garnet, ±staurolite, ±kyanite, ±plagioclase; (2) quartz, biotite, clinozoisite, ±calcite, ±hornblende, ±garnet, ±plagioclase. The garnets in these rocks show a wide variety of internal textures, including both S-shaped and straight S_i of fine-grained quartz, clinozoisite and iron-ore; and others with this type of S_i in the core, but with a margin of either clear garnet, or garnet with relatively large inclusions. (A 'large inclusion' in this context has a size approximately that of the groundmass crystals surrounding the garnet porphyroblast.)

Garnets with no apparent discontinuity in growth. Garnets within this class are those characterized by having, in addition to the possible presence of a very fine dusting (of graphite ?), inclusions of uniform size, with a straight, *S*-shaped, or random arrangement; or those which have no inclusions at all. In addition, these garnets show no sharply marked changes in inclusion pattern or refractive index when viewed in the optical microscope.

The majority of microprobe determinations have been carried out on garnets of this type, and with only rare exceptions a gradational compositional zoning with respect to FeO, MnO, MgO and CaO has been found to occur within individual garnets. This is illustrated in Figs. 1 and 2, which are based on point counts at selected locations across the garnets. In the oxide percentages shown, 'FeO' refers to total iron calculated as FeO, and all percentages are 'apparent concentrations' (that is, percentages uncorrected for absorption, atomic number, and fluorescence effects). The standards used were pure manganese, olivine (9·50 wt. per cent FeO, 49·08 wt. per cent MgO) (K. J. H.), pure iron and pure magnesium (B. H.), and wollastonite (47·44 wt. per cent CaO): the accelerating voltages used were 20 kV for iron, manganese and calcium, and 15 kV for magnesium; and the take-off angle was 40°. Thus the 'true concentration' of the oxide probably does not exceed the 'apparent concentration' by more than 10 per cent for FeO, MnO and CaO, and by more than 40–50 per cent for MgO; and since the last is generally less than 5 per cent by weight of the garnet the relative proportions of the oxides will be only slightly altered by correction.

Overall the most constant characteristic of the zoning observed is a gradual decrease of MnO and gradual increase of FeO from core to margin of the garnets. Forty-one out of forty-seven garnets in sixteen out of eighteen rocks from Sulitjelma show a decrease of MnO from core to margin (the other cases were unzoned), generally of from 2 to 5 per cent MnO, but not uncommonly of as much as 10 per cent MnO (see Fig. 1). FeO shows only a slightly less consistent variation in the opposite sense (but of similar magnitude), rarely remaining constant, or even decreasing slightly towards the margin. In the Glen Esk area garnets a maximum difference of 5 per cent MnO has been observed, but in the majority of cases MnO and FeO vary by only 1–2 per cent, as in Fig. 2; but despite its small size, the variation was found to occur in seventeen out of eighteen garnets (spread over seven rocks) examined for FeO, and seven out of eight garnets examined for MnO (the exceptional garnet in both cases showing no zoning).

For MgO the changes observed within the garnets from the Glen Esk area are very small and variable, but in the Sulitjelma garnets a general small increase from core to margin has been observed. CaO decreases from core to margin in seven out of eight garnets examined from the Glen Esk area, and in the one shown in Fig. 2 the zoning is exceptionally strong. Garnets investigated from the Sulitjelma region are not consistent with respect to CaO, which may increase, decrease, or remain constant from core to margin. Overall the general scheme of the zoning indicates the cation substitution to be:

$$\underset{\text{Core}}{Mn^{++}\ (+Ca^{++})} \rightleftarrows \underset{\text{Margin}}{Fe^{++}\ (+Mg^{++})}$$

Although the zoning in the garnets appears to be roughly concentric, preliminary investigations show that this is not always the case, either because of obvious fracturing or resorption later in the metamorphic history (Fig. 3), or in other cases possibly because of actual variation of growth rate in different directions during formation.

The possible factors involved in the production of this compositional zoning (which may be termed 'cryptic' since there is no indication of it under the optical microscope) are numerous, and it is difficult, with the information at present available, to determine which are the more significant. The general pattern of the zoning shows a change of chemical composition similar to that observed

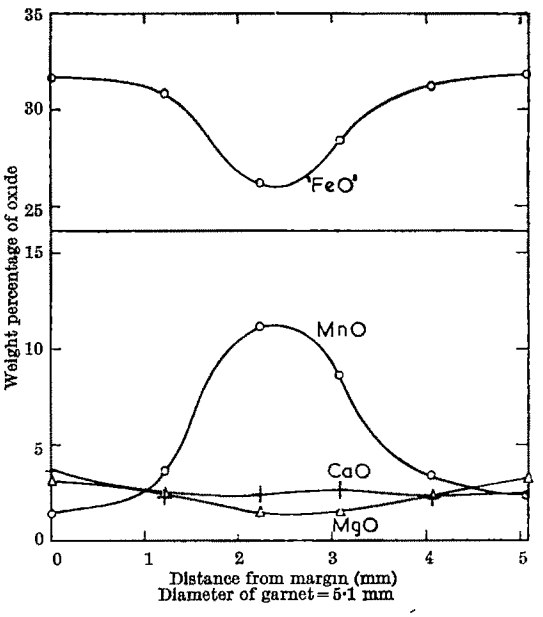

Fig. 1. Cryptic compositional zoning in an almanditic garnet from a garnet–hornblende–mica schist (64 *K* 323) from Sulitjelma, Northern Norway, as revealed by electron-probe analysis. The garnet is euhedral, contains few inclusions (unarranged), and optically appears to be of one phase of growth. The 'weight percentage of oxide' is the 'apparent concentration', that is, the concentration uncorrected for absorption, atomic number, and fluorescence effects (see text)

to occur with respect to grade in almanditic garnets from regional metamorphic sequences, where MnO and CaO decrease and FeO and MgO increase upgrade[4]. It seems possible, therefore, that the observed zoning of individual garnets is largely the result of a similar grade effect, namely, that as the grade increases during growth of the garnets Fe^{++} and Mg^{++} are increasingly stabilized in the lattice[1]. However, excluding metasomatism, other factors might cause similar effects, and one possibility, in connexion with the MnO zoning, arises from the marked affinity for garnet commonly shown by the small amount of MnO in metamorphosed argillaceous rocks[4]. In the rocks in question, practically the whole of the MnO is located within the garnets. It seems quite likely, therefore, that at the beginning of garnet growth (even under constant temperature and pressure conditions, at which both almandite and spessartite are stable), the MnO of the rock will become preferentially concentrated within the garnet; and considering the very small amount of MnO in the rock as a whole it will soon become exhausted in the vicinity of each garnet as the growth of the garnets proceeds. The process might be regarded as a fractionation of much of the rock MnO into the garnet early in the latter's growth, and thus effectively changing the amount of available MnO in the rock.

Other factors which might operate singly, or in combination with one another and those previously noted, in causing the zoning, include possible differences in the diffusion rates of the cations (either at constant or varying temperature), or increase in the available amount of Fe^{++} during metamorphism as a result of reduction of Fe^{+++} by reactions involving graphite[8]. In addition, the effects of chemical reactions involved in the production of other minerals within the rocks must be considered: the variable nature of the CaO zoning in the Sulitjelma rocks (where, in addition to plagioclase, the calcium-bearing minerals, calcite, clinozoisite and hornblende, may be present) as compared with the Glen Esk area rocks (where plagioclase is the only calcium-bearing mineral besides garnet) might be explicable on this basis.

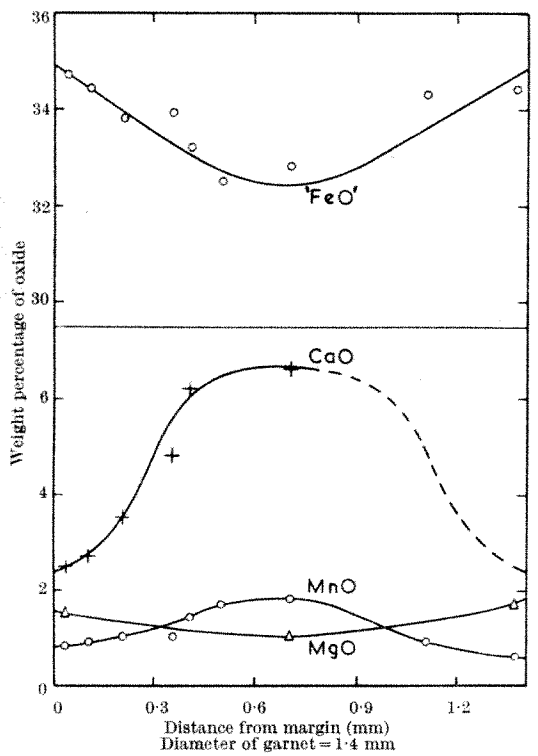

Fig. 2. Cryptic compositional zoning in an almanditic garnet from a garnet–staurolite–kyanite–sillimanite schist from Glen Esk, Scotland (specimen 96417–8, Harker collection, Cambridge), as revealed by electron-probe analysis. The garnet is approximately circular, has very slightly sigmoidal *Si* of fine-grained inclusions, and appears to be of one phase of growth. The 'weight percentage of oxide' is again 'apparent concentration', uncorrected for absorption, atomic number and fluorescence effects

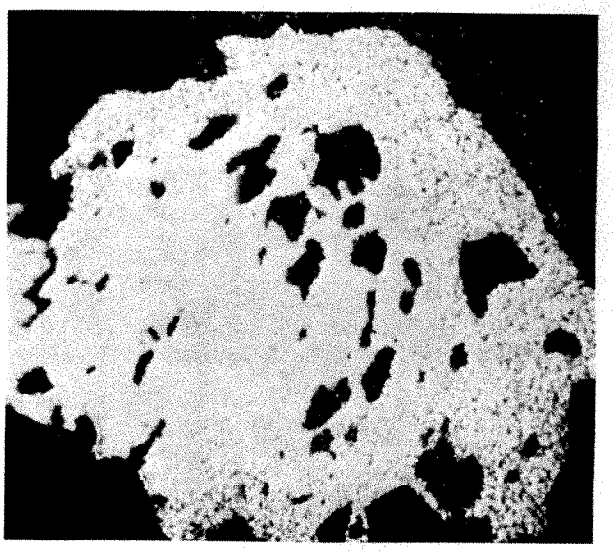

Fig. 3. X-ray scanning photograph taken in manganese K_α radiation of a cryptically zoned almandine garnet from a garnet–hornblende–mica-schist (64 *K* 131) from Sulitjelma, North Norway. The lightest area has the highest MnO content, and it can be seen that this is transgressed by the garnet margin. It is probable that this is due to fragmentation or resorption of the garnet after growth, especially since the lowest MnO content is associated with the (presumably) original euhedral faces. The dark inclusions and surround are quartz, clinozoisite, and biotite, containing only trace amounts of MnO

Garnets with an apparent discontinuity in growth. In the Glen Esk area the only garnets which suggest a possible discontinuity in growth have an interior densely dusted with fine irresolvable inclusions, sharply demarcated from a clear outer zone. Microprobe analysis across these garnets, however, has revealed no sharp change in composition between the clear and clouded parts, and such compositional zoning as exists is only of the gradational type described in the previous section.

Some garnets from the Sulitjelma region show marked evidence of a discontinuity in growth, with cores having straight or S-shaped *Si* of fine inclusions, and rims with large inclusions or none at all. In these cases a sharp change in composition does occur across the junction of the texturally different zones (Fig. 4). In general, FeO is usually greater in the outer zone, while CaO and MgO may either increase or decrease. MnO has never been observed to increase in the outer zone. These marked changes in chemical composition agree with the textural evidence in suggesting two distinct periods of garnet growth.

It may be noted that, except for slight zoning of plagioclase, none of the other minerals (hornblende, biotite, staurolite) investigated in the rocks described shows any compositional zoning.

General deductions. The present work has shown the existence of marked cryptic compositional zoning in virtually all almanditic garnets from different mineral assemblages, in two widely separated regions, and at grades of metamorphism varying from biotite zone to sillimanite zone. It is clear from this that there is a strong possibility that such zoning may occur in similar rocks from other regions, and that the interpretation of bulk chemical analyses of garnets must proceed with caution, both with respect to changes in garnet composition with grade, and also with regard to the partitioning of elements between co-existing phases. There is the possibility that bulk chemical analyses of garnets do not even represent the average chemical composition of the garnet in a rock, because of selective concentration of only one part of the garnet (such as the core) during

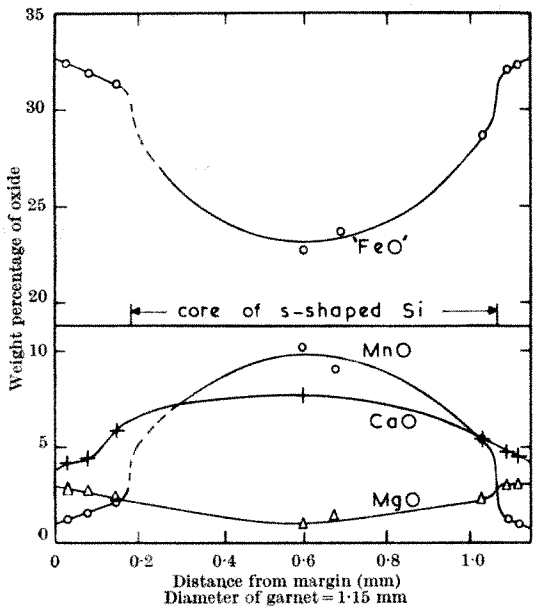

Fig. 4. Discontinuous compositional zoning in an almanditic garnet from a garnet–mica–schist (64 *K* 176) from Sulitjelma, Northern Norway, as revealed by electron-probe analysis. The garnet has a roughly circular core of S-shaped *Si* composed of fine-grained inclusions, and a euhedral margin of irregular thickness containing a few coarse, random inclusions. Thus optically it appears to be of two phases of growth, and this is also indicated by the compositional zoning. 'Weight percentage of oxide' again refers to 'apparent concentration'

separation of the mineral. Thus, one of us (K. J. H.), using magnetic and heavy liquid techniques, separated two pure fractions of garnet of slightly differing density from a garnet–mica–schist, in which there had been only one apparent phase of garnet growth. The distinct differences in chemical composition, especially of MnO, FeO and MgO, may be seen from the analyses of the two density fractions presented in Table 1.

The occurrence and nature of the zoning may, however, be useful in a number of ways. If it may be assumed that the change in composition (particularly of MnO) varies regularly during one phase of garnet growth, the occurrence of the zoning could prove a useful aid in studying such features as the frequency of nucleation, and the relative growth rates both of individual garnet crystals, and of garnets from different rocks, during the course of metamorphism. It may be noted that the data at present available might suggest that within one rock the smaller the garnet the smaller is the amount of zoning; however, further investigation with reference to the elimination of 'cut-effect' is necessary. In addition, the zoning, and variations in it, in different rock types and different areas, might provide some clues as to the chemical reactions occurring in the formation of particular mineral assemblages.

Table 1. ANALYSES OF TWO SEPARATED FRACTIONS OF GARNET FROM A GARNET–MICA–SCHIST (64 *K* 229) FROM SULITJELMA

	A	*B*
SiO_2	37·98	38·14
TiO_2	0·17	0·11
Al_2O_3	21·50	20·95
'FeO'	27·66	28·65
MnO	5·27	3·60
MgO	2·56	3·18
CaO	4·95	5·20
Total	100·09	99·83

The garnet is apparently of one phase of growth (few or no inclusions throughout) and *A* is the slightly denser fraction. It seems probable, from the differences in MnO, 'FeO', and MgO, that *A* is from nearer the core than *B*, but neither *A* nor *B* need necessarily represent the core or margin compositions respectively.

We thank Dr. J. V. P. Long for reading the manuscript and together with Dr. S. J. B. Reed for much useful discussion and invaluable help in using the electron-probe microanalyser, Dr. G. A. Chinner for critically reading the manuscript, and Prof. W. A. Deer for providing the facilities of the Department of Mineralogy and Petrology, Cambridge. The work was carried out during the tenure of research studentships at Cambridge, and University College, London, from the Department of Scientific and Industrial Research.

DISTRIBUTION OF SUBSTITUTIONAL NITROGEN DONORS IN SYNTHETIC DIAMONDS

By Inst. Lt. M. J. A. SMITH*, R.N., B. R. ANGEL* and Inst. Lt. Cdr. R. G. EMMONS, R.N.
Royal Naval Engineering College, Manadon, Plymouth, Devon

CONSIDERABLE attention has been devoted to the study of nitrogen impurity in natural diamonds using the technique of electron spin resonance[1–3]. The spectrum obtained is due to the unpaired electron provided by the substitutional nitrogen atom and the main feature is a triplet at $g = 2{\cdot}0024$ caused by interaction with the nitrogen nucleus which has a spin of unity. The distribution of nitrogen is variable and would seem to depend on the method by which the diamond was formed.

In the majority of natural diamonds nitrogen exists substitutionally in the form of non-paramagnetic platelets and such diamonds have recently been classified as Type I*a* (ref. 4).

Type I*b* diamonds contain nitrogen atoms which are not linked in platelet form. The electron spin resonance spectrum is usually narrow (0·3 oersted) and depends on the orientation of the static magnetic field to the diamond lattice. It has hyperfine constants $A = 40{\cdot}8$ oersteds and $B = 29{\cdot}2$ oersteds and typical concentrations lie in the range 10^{14}–10^{17} atoms cm^{-3}. A theory of the interaction for the nitrogen centre has been developed[1,3].

Samsonenko[2] observed electron spin resonance from nitrogen in natural diamonds and obtained two sets of superimposed lines of different widths. Line shape measurements indicated that the broad resonance was probably caused by dipolar interaction between nitrogen centres in regions of elevated concentration. He concluded that pairing of spins takes place and platelets are formed at concentrations of the order of 10^{20} atoms cm^{-3}. Exchange interaction should precede such pairing and evidence for this is provided by the Lorentz form of the central peak.

Huggins and Cannon[5] studied 'RVG'-type ('resinous vitrified grinding'-type) synthetic diamond and obtained the nitrogen spectrum superimposed on a broad resonance due to the transition metal catalyst used during preparation. The nitrogen resonance is considerably broader than is observed with natural diamonds and the three lines overlap considerably. More recent results by Dyer *et al.*[4] using samples of mean diameter 400μ strongly suggest

* Present address: School of Physics, University of Warwick, Coventry, Warwickshire.

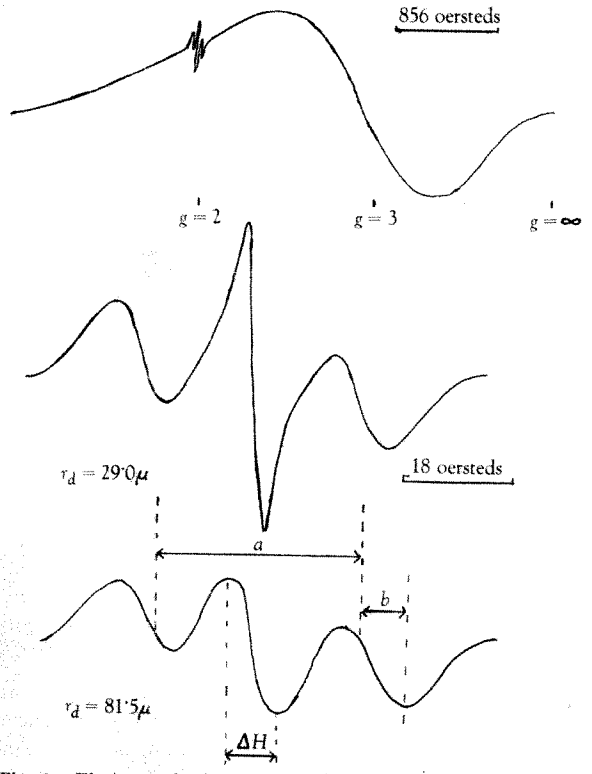

Fig. 1. Electron spin resonance spectrum for 'MBG'-type synthetic diamonds

that the major contribution to the line-width is produced by a spread in the local field due to ferromagnetic inclusions. For the nitrogen concentrations present, the satellite lines are broadened owing to the angular variation of the hyperfine coupling and the random distribution of the diamonds which form the sample. Evidence that nitrogen exists in platelet form is not obtained and synthetic diamond is thought to be wholly Type I*b*. The nitrogen content can be controlled during formation and can have a value up to about 10^{20} atoms cm^{-3}.

In the work presented here the electron spin resonance spectra have been recorded for a range of 'MBG'-type ('metal bonding grinding'-type) synthetic diamonds of different sizes. The diamonds are passed through sieves of known mesh and groups of the same mean diameter are isolated. Each diamond is assumed to be spherical and the diameter of a group is quoted as the mean mesh size of two consecutive sieves. A sample of constant weight, equal to 48 mg, is taken from the appropriate group and consists of between 6,000 and 130,000 single diamonds depending on the group diameter.

A typical spectrum is shown in Fig. 1. For the samples investigated, the concentration of paramagnetic transition metal impurity remains constant at approximately 10^{21} spins cm^{-3}. This is also true for specimens of 'MBS'- ('metal bonding saw') and 'RVG'-type synthetic diamonds which were studied, although *g*-value variations suggest a different catalyst. Ferromagnetic inclusions can clearly be expected.

Table 1 summarizes the results obtained for the nitrogen resonance. The spectrometer was calibrated against diphenyl picryl hydrazyl to obtain the concentration of paramagnetic centres and against methyl methacrylate monomer treated with nitric oxide[6] to define the magnetic field axis. The *g*-value of the central nitrogen resonance is 2·0024 ± 0·0007 and is in agreement with other published results. The splitting between the satellite lines (*a*) is 60 ± 2 oersteds and the width of each satellite (2*b*) is 20 ± 2 oersteds measured as shown in Fig. 1. These three parameters remain constant within the deviations quoted.

Table 1

r_d (μ)	N_{scc} Spins cm^{-3} × 10^{19}	ΔH Oersteds	$\left[\frac{N_d\|_{11\cdot7\mu}^{r_d}}{N_d\|_{0}^{11\cdot7\mu}}\right]$ Calculated
81·5	2·43	14·0	53
68·5	3·00	12·4	36
48·5	3·68	12·1	18
40·5	4·35	7·8	12
29·0	6·55	6·2	5

The concentration of paramagnetic nitrogen, N_{scc}, in the sample is given in the second column of Table 1 and is obtained by dividing the observed intensity by the total volume of diamond. It is clear that the concentration is not the same for diamonds of all sizes taken from the same batch and increases as they become smaller. One way in which the variation may be expressed is by plotting the concentrations in Table 1 against $1/r_d$, where r_d is the mean radius of the diamonds in a given sample. The graph obtained is linear (Fig. 2) and suggests that over the range investigated the number of paramagnetic nitrogen centres per cm^{-3} at a radius r cm within an individual diamond can be represented by the equation:

$$N_{cc} = \frac{K_1}{r} + K_2 \qquad K_1 = 1{\cdot}2 \times 10^{17} \qquad K_2 = 1{\cdot}8 \times 10^{18}$$

A similar relationship is obtained for 'MBS'- but not for 'RVG'-type diamonds. The latter inconsistency is believed to be caused by the irregular and elongated shape of 'RVG'-type diamonds for which the present experimental method is not suited.

Although the curve of Fig. 2 can equally well be fitted by an expression for N_{cc} involving exponentials, the foregoing expression is preferred since it provides at least as good an agreement with experiment, and is more convenient mathematically.

The observed spectra are made up of contributions from continuously varying concentrations of paramagnetic nitrogen, each element of which will have an associated line width. The surface values of N_{cc} are approximately equal to 0·7 N_{scc}. Using the foregoing expression for N_{cc} it is now possible to calculate the position within a diamond at which the paramagnetic nitrogen concentration has reached 10^{20} atoms cm^{-3}. The value obtained is 11·7μ. Exchange interaction and possible pairing of spins should be observed in this region.

The reduction of width of the central resonance (ΔH in Fig. 1) may be explained if it is assumed that an exchange narrowed resonance is obtained from nitrogen in the inner regions of a diamond at a radius less than 11·7μ. There are approximately 10^{12} paramagnetic centres per cm^3 within the 11·7μ radius sphere, and the mean concentration is 1·5 × 10^{20} cm^{-3}. The expression for N_{cc} used to fit the experimental results cannot be assumed to hold below 11·7μ but it is assumed to be valid down to this value. The fourth column in Table 1 lists calculated values of the ratio of the number of paramagnetic nitrogen centres contained within the inner sphere of radius

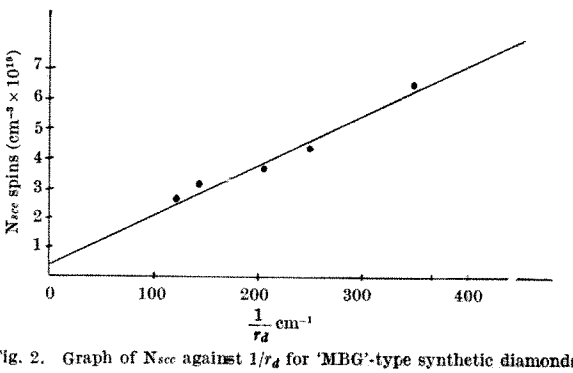

Fig. 2. Graph of N_{scc} against $1/r_d$ for 'MBG'-type synthetic diamonds

11·7μ to the number of such centres contained within the shell defined by the inner sphere and the surface:

$$N_d\Big|_{11\cdot7\mu}^{r_d} = 4\pi\int_{11\cdot7\mu}^{r_d} N_{cc}r^2dr$$

and:

$$N_d\Big|_{0}^{11\cdot7\mu} = \frac{4\pi}{3}\, r_d^3 N_{scc} - N_d\Big|_{11\cdot7\mu}^{r_d}$$

$N_d\Big|_{0}^{11\cdot7\mu}$ is constant for all samples and is of the order 10^{12}. These ratios indicate, as observed, that the contribution of an exchange narrowed signal to the total resonance is small for diamonds of $r_d = 81\cdot5\mu$ but has become important for $r_d = 29\cdot0\mu$.

For the concentrations present, the line-widths are too large to be accounted for by dipolar interactions between nitrogen centres distributed randomly throughout the lattice, using the relationship $\Delta H \sim N_{cc} \times 10^{-19}$ oersteds[7]. Ferromagnetic inclusions appear to offer a proven explanation[4].

Random orientation of a large number of diamonds will produce an asymmetrical broadening of the satellite resonances but not of the central peak. The effect, although present, is not very marked in these experiments owing to the broadening produced by the ferromagnetic inclusions which affects all three lines.

Further experiments are in progress to reduce the size of synthetic diamonds by etching and preliminary results are in agreement with the foregoing conclusions. It should be of interest to investigate small synthetic diamonds.

We thank Captain W. B. S. Milln, Royal Navy, for permission to publish this work. We also thank Mr. L. Bullock and Mr. M. A. L. Bracegirdle of Messrs. Bullock Diamond Products, Ltd., who supplied the samples, and Plymouth College of Technology for their co-operation.

FLOW PATTERNS IN A SUBMERGED LIQUID JET DIFFUSING UNDER GRAVITY

By DR. S. K. A. NAIB
Fluid Mechanics Laboratory, West Ham College of Technology, London

WHEN a stream passes under a submerged sluice gate into water on the downstream side, it forms a jet which goes far downstream before it is dispersed. The physical aspects of the dispersion of such a jet have some similarity, both qualitatively and quantitatively, with the simpler problem of the diffusion of fluid jets[1]. However, the flow of an air jet discharging from a slit into the atmosphere is not affected by adjacent boundary restrictions. A sluice-way jet, on the other hand, disperses into restricted surrounding fluid and has several fundamental properties which distinguish it from a free air jet. Apart from the contraction effect due to the sharp edge of the gate, the differences are as follows.

The jet issues into a slow-moving medium and is bounded on one side by a solid boundary and on the other side by a free-water surface. The mixing process between the jet and the surrounding fluid causes part of the latter to be carried forward with the jet under conditions in which both the forward momentum and discharge are conserved. This entrainment leads to recirculation to replace the fluid entrained; thus a zone of circulation is established on top of the jet which is usually termed a 'roller'. Meanwhile, the mixing process causes the jet to expand laterally until its upper mean flow line reaches the free surface. This point is the stagnation point which defines the downstream end of the circulation zone.

In comparison with the free jet, the chief difference lies in the presence of the circulation zone. There is also the difference that in the sluice jet the upper stream or limit of the flow is a surface which is free from shear stress and slopes upward in the downstream direction, indicating that the diffusion process takes place under a pressure gradient, often of considerable magnitude.

The rise of pressure in the direction of flow is associated with the conversion of some of the kinetic energy of the high-velocity jet into pressure. The resulting difference of pressure influences the discharge through the sluice-way and also influences the nature of the flow patterns downstream as indicated in Figs. 1 and 2. The former concerns variation in downstream depth with the Froude number of the flow $F_1 = q/\sqrt{gd_1^3}$, where q is the unit discharge and d_1 is the contracted depth of the jet. The measurements were taken in a 4-in. wide glass flume having an outlet weir for adjusting the downstream water level, the upstream depth being kept constant at 7·5 in. The latter shows a number of photographs, exposure 0·2 sec, selected to describe the kind of patterns which occur under the particular conditions marked *a–e* in Fig. 1. The photographs were taken with a 'Zeiss Ikon' camera of picture size 9 cm × 12 cm, with the flow illuminated by a mercury–vapour discharge lamp flashing at 100 times a sec. The tracers were droplets of a new white emulsion discovered experimentally by the author by mixing a mixture of olive oil and nitrobenzine, prepared to the same density of water, with a suitable percentage of water. Some idea of the scale of the photographs may be obtained by noticing the sluice opening which is 2 in. deep.

At a low rate of flow, the jet flows under the gate and apparently a sharp interface exists between the jet and

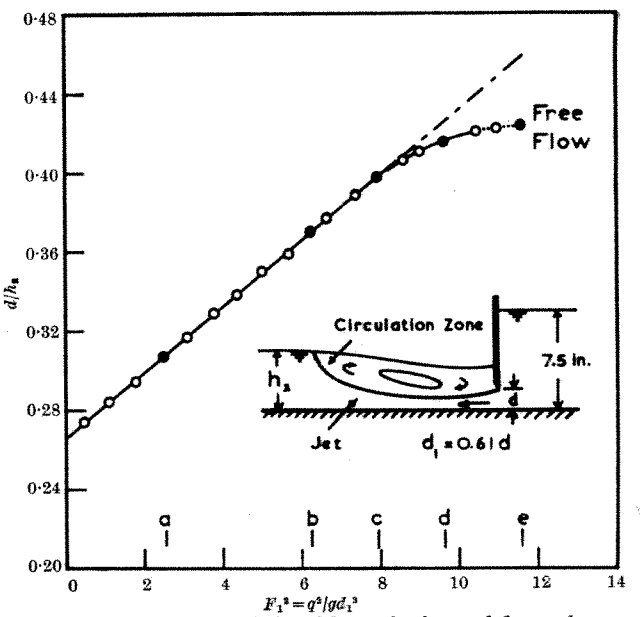

Fig. 1. Discharge characteristics of free and submerged flow under a sluice gate

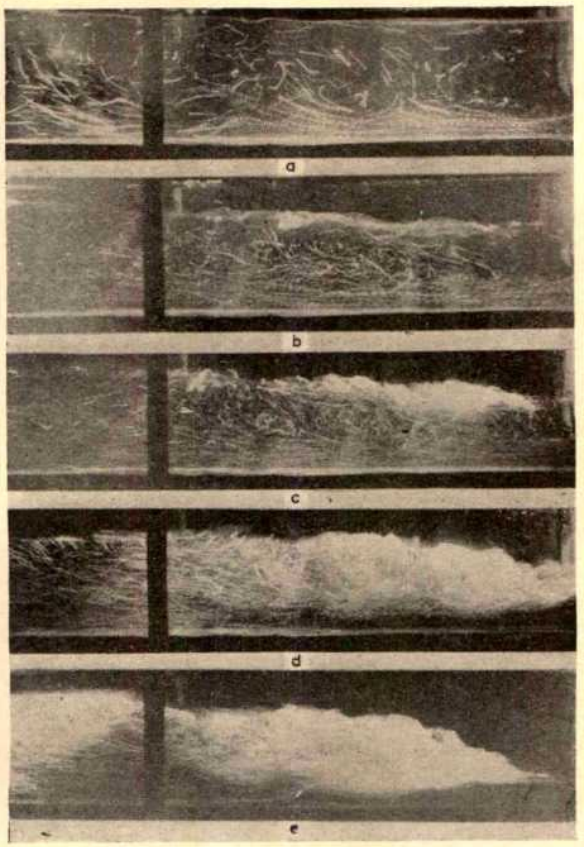

Fig. 2. Photographs of the flow patterns in the sluice-way jet for different discharges

the water above it (Fig. 2*a*). This interface persists for a distance of several sluice openings but becomes contorted with billows and hollows as a result of the development of large-scale eddies between the jet and the overlying fluid. When the rate of flow is increased by lowering the downstream level, the jet boundary breaks up into large vortices at a point nearer the gate (Fig. 2*b*). In this photograph, the diverging character of the jet is more apparent and the length of the circulation is shorter. These are typical changes though the photographs are momentary. At the next higher rate of the flow (Fig. 2*c*) the jet continues to behave in the same characteristic manner, though the large eddies now extend up to the free surface, with the result that a new surface effect comes into play: air is entrained at the occasional discontinuities produced by the strong vortex motions. Further, it is at this point that the straight line law of the discharge curve (Fig. 1) terminates and transition begins and continues until the jet discharges freely into the air.

In the transition zone, a further increase in the rate of flow results in the formation of a train of vortices, as shown in Fig. 2*d*. The vortices appear practically at the gate and they are packed with air bubbles, which swell their volumes. With distance, the vortices appear to increase in bulk and to decrease in translational velocity, until at the end of the circulation zone they appear to lose distinction and are merged in the general turbulence. A region of violent turbulence thus extends throughout the flow the structural features of which, however, remain similar to those shown in Fig. 2*a*, and resemble those of a wake flow behind a two-dimensional bluff body.

With decreasing downstream level, the depth at the gate becomes less and less until at a certain discharge the jet carries the water forward and the jet issues free from the gate. Diffusion then occurs further downstream under considerable pressure gradient, involving the phenomena called traditionally the 'hydraulic jump' (Fig. 2*e*). The dotted part of the discharge curve, Fig. 1, represents flows where the front of the jump is somewhere between the gate and the vena contracta section, about two gate openings downstream. It is interesting to note that the slope of the water surface, forming the upper boundary of the jump circulation zone, is about 1 in 4; this is practically the same as the rate of spreading of the outer boundary of a plane air jet.

Recently[2], I have investigated the diffusion of the jet under submerged conditions using a photographic technique. Owing to the entrainment of air bubbles, the flow under transition conditions could not be included. For the same reason, Rouse, Siao and Nagaratnam[3] investigated the turbulence characteristics of the hydraulic jump by stimulating the flow pattern in an air duct.

I thank Prof. C. M. White, Imperial College of Science and Technology, London, for advice.

INVESTIGATION OF RIBONUCLEASE ISOZYMES BY AN ELECTROPHORETIC ULTRA-VIOLET METHOD

By Dr. NEWTON RESSLER*, EDWIN OLIVERO, Dr. GEORGE R. THOMPSON and Dr. RAMON R. JOSEPH
Department of Medicine, Wayne County General Hospital, Eloise, Michigan

CHROMATOGRAPHIC and immunoelectrophoretic investigations have demonstrated that a given tissue may contain a number of different molecular species of ribonuclease[1]. Immunoelectrophoretic analysis characterizes individual isozymes on the basis of mobility, but requires the preparation of antiserum, and does not provide direct visualization of the individual isozyme bands. Poort and van Venroy have referred to a method for detecting nucleases after electrophoresis[2]. It involves incubating the electropherogram while in contact with an agar slide containing dissolved substrate. The substrate slide is then placed in an acid solution, which precipitates the unreacted ribonucleic acid (RNA), but leaves the areas of nuclease activity as transparent spots. This procedure has the disadvantages that it may provide only a fleeting view of isozymes in low concentrations, and various proteins diffuse into the substrate layer. This also produces clear areas, which may be difficult to distinguish from areas of enzyme activity. However, the method has been useful when carried out with that described here.

Markham and Smith previously published a dialysis method for separating products from the reaction of RNA with ribonuclease[3]. The nucleotides produced, of smaller molecular size than the unreacted RNA, diffused through the dialysis membrane and were collected in the dialysate.

* Present address: Department of Pathology, University of Michigan, Ann Arbor, Michigan.

It therefore seemed possible that, by permitting the separated isozymes to react with RNA while in contact with dialysis membrane, the reaction products would selectively diffuse through the membrane and could be detected in an agar layer on the opposite side.

Human tissues were obtained at autopsy, and were homogenized in 2 ml. of distilled water per gm. Leucocytes were prepared by a modification of the method of Christlieb *et al.*[4]. Human serum or tissue homogenates were subjected to electrophoresis essentially as previously described[5]. Agarose was added to the buffer to a concentration of 0·4 per cent. It was dissolved by heating to a boil. 100 ml. of this solution were poured over a 6 × 10 in. glass plate, which had been bordered by gluing plastic strips along the edges. The plate was connected by electrode vessels, containing the same buffer as the agarose layer, by means of thick filter paper strips (Schleicher and Schuell No. 900). After the agarose layer cooled, a separate strip of Whatman No. 17 filter paper about 2 × 10 mm was wet with each sample to be applied, lightly blotted, and then inserted in the agarose layer. The plates were covered to prevent evaporation and current was applied overnight (16 h).

At the end of this period, 40 ml. of a 0·1 M phosphate buffer, *p*H 7·25, in which 1 per cent Difco 'Noble' agar had been dissolved, was poured over a 6-in. square quartz plate (also bordered at the edges). After the agar hardened cellulose dialysis tubing (Viscose process, 0·0016 in. thick) was cut along one side, spread open as a single sheet, washed in water, and placed over the agar layer. Air bubbles between the agar and dialysis membrane were avoided.

A solution containing 1 per cent yeast ribonucleic acid (Nutritional Biochemicals Corporation), 0·1 per cent agar, and 0·1 M sodium phosphate, at a *p*H of 7·25, was added and uniformly spread over the portion of the agarose layer in which the samples had been electrophoresed. The agarose, coated with substrate, was then inverted and placed on the dialysis membrane upside down. This was done by supporting the plate containing the agarose layer, upside down, about 0·5 in. above the dialysis membrane, and sliding a fine wire between the agarose layer and the glass plate until the agarose dropped on the dialysis membrane.

Fig. 1 presents a diagrammatic representation of the arrangement. The entire preparation was covered to prevent evaporation, and incubated at 37° C for 3 h. The incubation provided the opportunity for products from the reaction of RNA with ribonuclease to diffuse down through the dialysis membrane into the underlying agar layer. After the incubation, the dialysis membrane and agarose layer were removed and discarded. The agar, layered over the quartz plate, was then photographed at a wave-length of 260 mμ using monochromatic light and 'commercial' Kodak film placed below the plate.

To detect acid instead of alkaline ribonuclease, the *p*H's of the ribonucleic acid solution, and of the agar layer over the quartz plate, were adjusted to 5·2. To facilitate bringing the agarose layer to this *p*H, it was first covered with a 0·1 M acetate buffer, *p*H 4·6. The ribonucleic acid solution at a *p*H of 5·2 was then spread over the agarose.

Ribonuclease isozymes were also visualized by the procedure referred to by Poort and van Venroy[2]. 60 ml. of a warm solution containing 1 per cent agar dissolved in a 0·1 M phosphate buffer was added to and mixed with 32 ml. of a 1·8 per cent solution of ribonucleic acid in a 0·1 M phosphate buffer. The *p*H's of the aforementioned solution had been adjusted to 5·2 or 7·25 for the acid or alkaline ribonucleases, respectively. The mixture was poured on to a bordered 6 × 10 in. glass plate. After the gel had hardened, the agarose layer containing the samples separated by electrophoresis was inverted and placed on the gel, as already described. The plate was sealed, and kept 16 h at room temperature. The agarose layer was then removed and discarded. The plate was inserted in a solution of 0·5 N hydrochloric acid. The unreacted ribonucleic acid formed a white precipitate in the hydrochloric acid. Clear areas where the precipitate did not form indicated the presence of ribonuclease isozymes.

Total ribonuclease-levels were determined by the method described by Levy and Rottino[6]. The *p*H of the ribonucleic acid solution was adjusted to 7·25 after the nucleic acid had been added rather than before. (This was also done in the preparation of the solutions described here.) For total levels of acid ribonuclease, the *p*H was adjusted to 5·2. All determinations were undertaken in duplicate. Total ribonuclease-levels were also determined for sections of agarose, along the migration path. A section of the agarose was added to each tube, which was diluted to 1 ml. with the buffer used for electrophoresis. The substrate was then added, and the procedure was as before. Blanks and standards were also prepared in the same manner (except for the omission of agarose, which, as control experiments demonstrated, did not affect the results).

After electrophoretic separation, a sample of human serum was analysed for ribonuclease distribution by the ultra-violet absorption procedure described previously, by the method of Poort and van Venroy, and by measuring total ribonuclease-levels of agarose sections along the migration path. The results obtained by the three procedures are consistent, and are presented in Fig. 2. The electrophoresis was conducted in a buffer containing 0·05 M/l. of glycine and 0·03 M/l. of lithium chloride. It had been adjusted to a *p*H of 8·7 with sodium hydroxide. 55 V were applied. The densitometer curve of the ultra-violet photograph was obtained by printing the negative on a transparent base, and measuring the optical density of this print along the migration path. The curve from the plate obtained by the procedure of Poort and van Venroy was obtained by inserting the ribonucleic acid gel strip in a densitometer, and measuring the relative percentage of transmission along the migration path. Although neither of these latter two curves is quantitative, both indicate the same general ribonuclease isozyme distribution as the optical density curve of total levels of individual sections; that is, a doublet on either side of the site of sample application (not clearly resolved in this separation, but seen more clearly below), and a less concentrated isozyme behind the γ-globulin. The electrophoretic curve of the doublet is not grossly different from that obtained by Rabinovitch and Dohl with ribonuclease purified from guinea-pig serum[7].

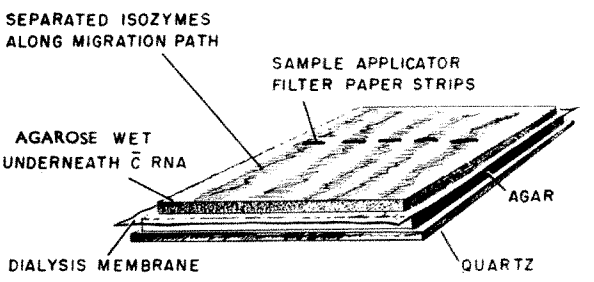

Fig. 1. Arrangement for the incubation of separated ribonuclease isozymes with RNA

Agar had originally been used, instead of agarose, for the electrophoretic separation of the samples. In this case, the principal isozymes had a variable mobility which ranged from that of an α-globulin to that of a pre-albumin. It was also observed that isozymes migrated less rapidly towards the anode when more concentrated. The difference in the results obtained by substituting agarose for agar suggests that the isozymes were interacting with an anionic component of the agar, as has previously been observed with lactic dehydrogenase isozymes[8,9]. Ribonuclease

interactions, however, are apparently more extensive, since such interactions would not occur with lactic dehydrogenase under the already-described conditions.

Kidney homogenates were subjected to electrophoresis in the glycine buffer already used, in the same buffer diluted 1 to 2, and in a 0·1 M phosphate buffer of *p*H 7·25. Agarose was used on all occasions. The results are presented in Fig. 3. In the diluted glycine buffer, interactions are extensive, even with agarose, and all isozymes move as a smear towards the anode. In the more concentrated glycine buffer, these interactions are greatly reduced, although some of the isozymes still appear to be displaced by interactions towards the anode. In the phosphate buffer, interactions are no longer apparent. Isozyme mobility was found to be independent of its concentration with this buffer, but not with the glycine buffer.

Ribonuclease isozymes have also been detected after separation by starch-gel electrophoresis. The gel strip was incubated in contact with the dialysis membrane as done with the agarose strips. The bands obtained were not sharp and the starch gels did not appear to offer any advantage over agarose for this application.

Fig. 4 shows a human serum ribonuclease isozyme pattern. The most intense band (strip *a*) has a mobility approximately that of normal adult haemoglobin, while less-intense bands can be detected near the site of application, and behind the γ-globulin. The forward band is more intense at a *p*H of 7·25, while the band behind

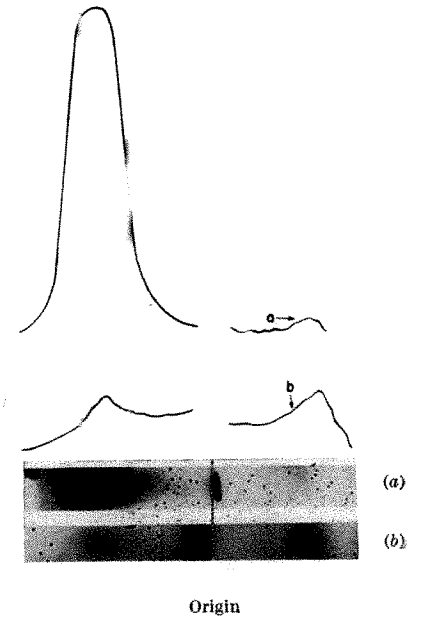

Fig. 4. Ribonuclease distribution in human serum, after incubation at a *p*H of 7·25 (*a*) and 5·2 (*b*). Electrophoresis had been conducted in the 0·05 M glycine buffer. Densitometer curves, depicted here, were obtained from prints of ultra-violet negatives

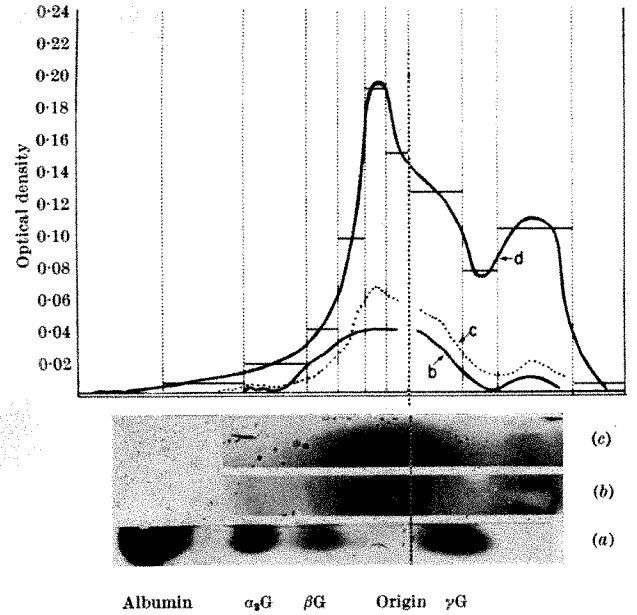

Fig. 2. Comparison of methods for detection of ribonuclease distribution in human serum. Bottom strip (*a*) is stained for total proteins. Strip (*b*) and curve (*b*) (relative percentage of transmission) were obtained by the method of Poort and van Venroy. Strip (*c*) and curve (*c*) (relative optical density) were obtained by the ultra-violet method. Curve (*d*) (optical density, scale on the left) represents determinations undertaken on sections along the migration path, cut as indicated by the horizontal lines. Migration towards the anode is to the left, throughout

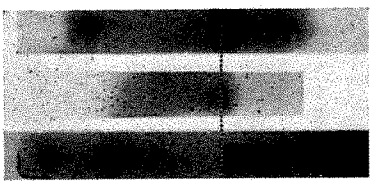

Fig. 3. Ribonuclease distribution in human kidney homogenates, (ultra-violet method), after electrophoretic separation in a 0·05 M glycine buffer *p*H 8·7 (*a*), in a 0·025 M glycine buffer *p*H 8·7 (*b*), and in a 0·1 M phosphate buffer (*c*), *p*H 7·25. (Speckles were caused by air bubbles)

γ-globulin is relatively more intense at a *p*H of 5·2. Various sera have been investigated, but no isozymes in addition to those shown previously have been detected.

The type of sera used, and their total ribonuclease-levels, are presented in Table 1. The values obtained with normal sera are similar to those reported by Levy and Rottino[6] and by Herriott *et al.*[10]. So far as we can trace, acid ribonuclease has not been detected in human serum previously. Its concentration in normal serum is so low that it might not exhibit a discernible peak when the *p*H is plotted against activity.

Table 1. RIBONUCLEASE-LEVELS IN HUMAN SERUM

Patient No.	Alkaline ribonuclease (μg per ml.)	Acid ribonuclease (μg per ml.)	Alkaline–acid ratio	Diagnosis
1	0·21	0·05	4·3	Apparently normal
2	0·25	0·04	6·1	Apparently normal
3	0·22	0·05	4·4	Apparently normal
4	0·18	0·03	5·9	Apparently normal
5	0·22	0·04	5·5	Apparently normal
6	0·255	0·05	4·7	Pernicious anaemia
7	0·37	0·08	4·6	Macrocytic anaemia
8	0·225	0·04	5·3	Atherosclerotic heart disease
9	0·29	0·08	3·7	Laennec's cirrhosis
10	0·54	0·25	2·15	Disseminated cancer of the liver, haemolytic anaemia
11	0·31	0·14	2·2	Chronic granulocytic leukaemia
12	0·37	0·17	2·1	Chronic myelogenous leukaemia, anaemia
13	0·45	0·14	3·2	Disseminated cancer of the colon

Ribonuclease patterns found with solutions obtained from cells of erythrocytes and leucocytes are presented in Fig. 5. A preliminary comparison was made of the leucocytes from two patients with leukaemia to the leucocytes from two apparently normal individuals. No obvious difference was found except for the possibility that the isozyme most rapidly migrating towards the anode was relatively more intense in the leucocytes from the two leukaemic patients than in the leucocytes from the normals. This isozyme would seem to be comparatively

unstable, and its intensity decreases during storage at 4° C at a greater rate than the other isozymes.

Some examples of total ribonuclease-levels of haemolysates of erythrocytes are shown in Table 2. The concentrations of ribonuclease in normal erythrocytes were relatively low. In certain cases of anaemia, however, the concentrations were considerably elevated.

Ribonuclease isozyme patterns of some normal human tissue homogenates are presented in Fig. 6. The kidney and liver, in particular, have isozymes with similar mobilities. In this connexion, the same five lactic dehydrogenase isozymes are believed to occur, in different relative concentrations, in the various tissues of the body[11], and it is possible that the same ribonuclease isozymes may also occur in more than one tissue.

Houck and Berman have suggested that the ribonuclease in serum is derived from leucocytes[12]. In some instances (such as cases of congestive heart failure), they did not find any apparent correlation between the white blood cell count and the serum ribonuclease-level. There also did not seem to be any correlation between the serum ribonuclease-level and the white blood cell count in the cases presented in Table 1.

The mobility of the most concentrated ribonuclease isozyme in serum does not correspond to that of the most intense band of leucocytes, Fig. 5. The isozyme in serum which migrates behind the γ-globulin towards the cathode (an acid ribonuclease) does, however, correspond in mobility to the most intense band of the leucocytes. (Kidney, liver and erythrocytes also exhibit an isozyme with the same mobility.)

The isozyme distribution in erythrocytes is similar to that in leucocytes. The low level of alkaline ribonuclease in normal erythrocytes makes it unlikely that serum ribonuclease is derived from this source. The alkaline–acid ratios are different in serum than in erythrocytes, and a high erythrocyte acid ribonuclease value may occur with a low acid ribonuclease level in the serum (see, for example, patient No. 6 in Tables 1 and 2).

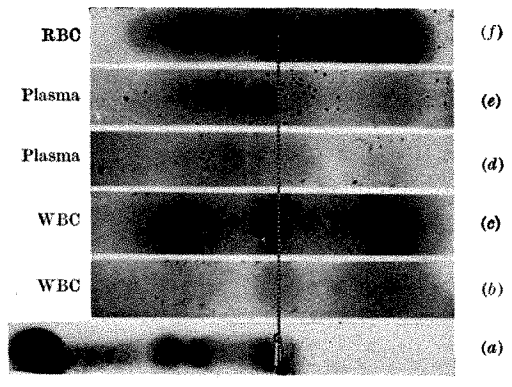

Fig. 5. Ribonuclease distribution in leucocytes and erythrocytes. The bottom strip (*a*) was stained for total proteins. Strips (*b*) and (*c*) were obtained from leucocytes, strips (*d*) and (*e*) from plasma, and strip (*f*) from erythrocytes. Strips (*b*), (*c*) and (*d*) were prepared by the method of Poort and van Venroy. Strips (*e*) and (*f*) were prepared by the ultraviolet method. All samples were from patient No. 12 in Table 1, except strip (*b*) which was from subject No. 4. The electrophoresis had been undertaken with the 0·1 M phosphate buffer, and the incubations had been conducted at a *p*H of 5·2

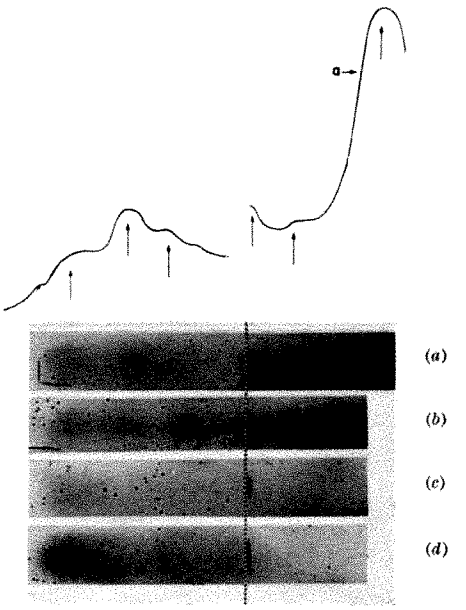

Fig. 6. Ribonuclease distribution in tissue homogenates. The homogenates were from kidney (*a*), liver (*b*), heart (*c*), and testes (*d*). The densitometer curve of the kidney homogenate was made from a print of the ultra-violet negative. Peaks are indicated by arrows. The electrophoresis was done with a 0·1 M phosphate buffer, and the incubations were conducted at a *p*H of 7·25

The procedure described here may also be applicable to the detection of isozymes of deoxyribonuclease, and we hope to investigate this possibility in the near future.

We thank Dr. Robert Schmidt, of the Department of Pathology, for tissue samples, obtained at autopsy. This work was supported by a grant from the U.S. Public Health Service.

CELLULAR CONTROL SYSTEMS AND RADIOSENSITIVITY

By J. S. ORR, C. S. HOPE and JEAN LAURE

Regional Physics Department, Western Regional Hospital Board, Glasgow

AND

DR. J. M. STARK

Department of Bacteriology, University of Glasgow

RADIOBIOLOGICAL experiments and clinical experience suggest that cells do not necessarily respond to irradiation as individual autonomous units and that local interactions controlling proliferation of normal cells in tissue can be altered. Theory and experiment together reveal a strong association between temporal properties of cellular control systems and radiosensitivity.

It is generally accepted clinically that fractionation is beneficial and that the shape of the time-dose curve for most tissues is convex upwards. More precise experimental data on the skin response in pigs have confirmed this form of time-dose curve[1]. However, the usually accepted shapes for cell survival curves are not in accord with these observations. For example, the two survival curves in Fig. 1*a* can be considered to apply to populations of normal and tumour cells in solid tissue. Fractionation régimes can be applied to both populations which always result in the same survival of the tumour cells. The effect of such fractionation is shown in Fig. 1*b* to be only slightly beneficial, in that the increase in the survival of the normal cells is small. Also the time-dose curve for the normal population (Fig. 1*c*) is concave upwards. Agreement with observation is obtained, however, if the survival curves are assumed to have the shapes shown in Fig. 2*a*, where the curve for the normal cells has a further bend. If the same fractionation régimes are used, the curve in Fig. 2*b* shows that fractionation has been very beneficial and the time-dose curve (Fig. 2*c*) is convex upwards. The need for the extra bend to produce time-dose curves of this shape has been recognized for some time[2]. Hornsey and Vatistas[3] have shown with 4-day death in mice that the D_Q at the survival level used is greater than 400 r. This implies a curve with a lower bend since the damage at 200 r. is still reasonably large[4]. With fractionated doses the lower bend would be expected at a fixed survival rather than at a fixed total dose, if the mechanism causing it is subject to a repair process. Therefore the survival curve for normal cells in Fig. 2*a* is considered as representing only single dose results, and the curves of Fig. 2*b* and Fig. 2*c* have been derived by considering the bend to occur at a fixed survival.

There is evidence that this shape of survival curve arises largely from a change in the local interactions between cells, and that an absence of local interaction is associated with an absence of the bend. For example, Stoker[5] has shown that a confluent layer of irradiated polyoma-transformed cells can inhibit colony formation

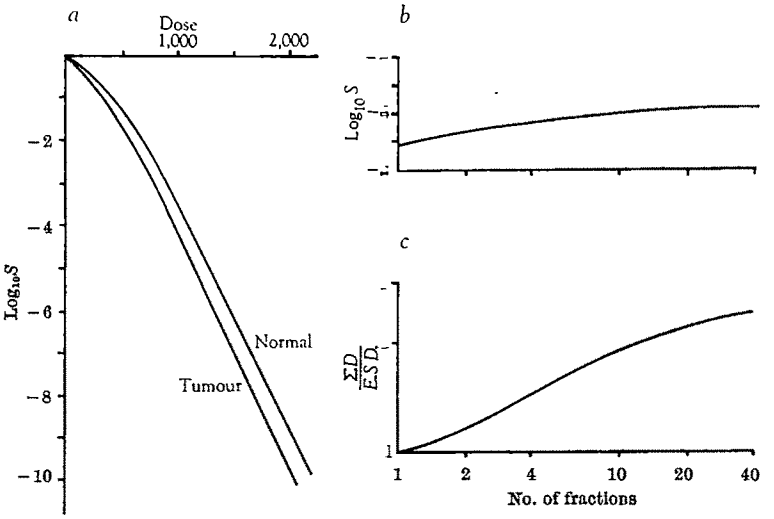

Fig. 1. (*a*) Assumed survival curves. (*b*) Effect of fractionation on survival of normal cells. (*c*) Time-dose curve for normal cells

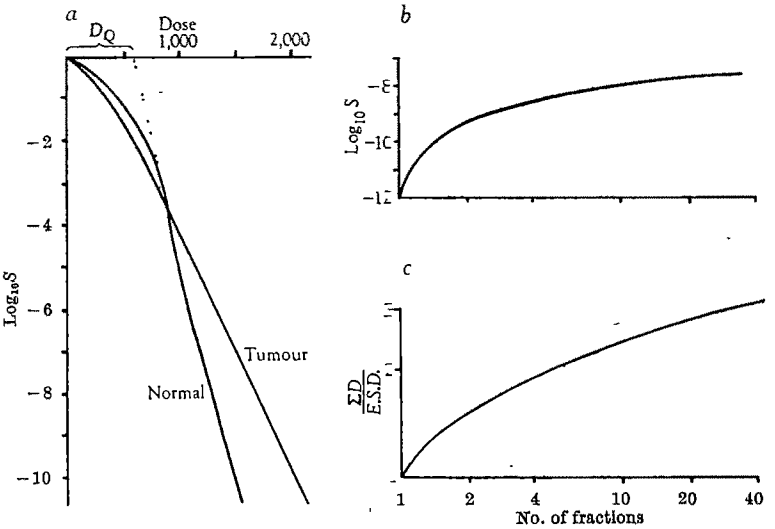

Fig. 2. (*a*) Assumed survival curves. (*b*) Effect of fractionation on survival of normal cells. (*c*) Time-dose curve for normal cells

by non-irradiated cells from the same clone. When the non-irradiated cells were separated from the irradiated layer by 0·6 mm of agar medium, the inhibition almost disappeared. A survival curve deduced from this behaviour has a lower bend. Furthermore, highly anaplastic cells do not show this inhibition after irradiation, and the lower bend is not found in survival curves obtained from solid tumours of such cells[6]. There is very little evidence on the nature of this effect on cellular interactions, although, as the effect is an inhibition of mitosis, it may be mediated by chalones of the normal intercellular control system[7].

A tendency to show periodic oscillations is a natural consequence of the interdependence of the parts of an organized biological system, and forms a cogent relationship between a number of aspects of cellular control. A theory of intracellular control has been developed mathematically by Goodwin[8], based on equations derived from recent evidence about the molecular mechanism of the control. This theory shows how oscillations can arise in cellular control systems.

A striking experiment by Harker[9] suggests the great importance of the phases of such oscillations. The experiment was performed on cockroaches, which have a well-defined neuro-secretory gland maintaining a strong autonomous periodicity in hormone secretion. When individuals received successive transplants of the glands of other individuals which had been living under similar conditions, there were no ill effects. When, however, the donors of the transplants had been living in an environment with a reversed day and night cycle, nearly all the recipients rapidly developed metastasizing transplantable tumours in organs remote from the site of implant. In this experiment malignancy has been caused by phase perturbation. Further, the relative lengths of the parts of the cell cycle are different in normal, hyperplastic and malignant cells from the same tissue[10], which again associates differences of cellular phase with important differences in cellular control. The control system defect manifested by neoplasms of progressive degrees of malignancy in ageing organisms may be a gradual slip in these relative phases.

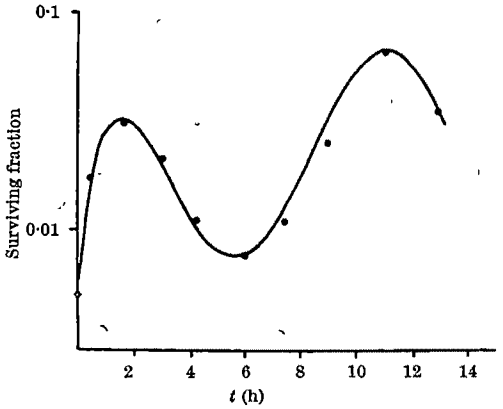

Fig. 3. Curve derived from the model for the variation in surviving fraction after two irradiations separated by t (h). The points are from the experimental results of Elkind *et al.* (ref. 13)

A growing volume of evidence supports the association of radiosensitivity with cellular control systems. In almost all systems investigated[1,3,11], an oscillation in radiosensitivity can be exhibited by suitable fractionation experiments on a short time-scale. Good agreement with experimental two-dose results can be obtained from a model in which the viability of the cell is linked to a substance represented by one of the variables in equations like Goodwin's, as suggested by Pohlit[12]. The assumptions are made that the amplitudes of the oscillations are fairly small compared with their mean value, and that the number of lethal injuries produced by irradiation is inversely proportional to the concentration of the substance. This last-mentioned assumption bears on the important, but rather neglected, problem of the mechanism of lethality. For the sake of simplicity, the equations are regarded as being linear with a solution of the form $[A \cos (wt + \psi) + B]$, where the capital letters in this and later expressions represent suitable constants. Most of the potential survivors of the first irradiation will be those in which the initial concentration was high, so ψ can be taken as zero. Therefore, the number of lethal injuries per cell produced by a first irradiation at time zero and a second at time t is proportional to $[C - D \cos wt]$. It has been shown that the initial rise in the radiosensitivity curve is due to recovery, which is a cellular process of a different type to the main oscillation[13,14], so C is taken to be $C\infty + e^{-at}(Co - C\infty)$. The number of lethal injuries per cell is therefore proportional to $[C\infty + e^{-at}(Co - C\infty) - D \cos wt]$, and as their distribution is a Poisson distribution, their number is proportional to minus the natural logarithm of the surviving fraction. Fig. 3 shows that when suitable values are inserted for the constants, the equation produces a curve which is a good fit to the experimental results of Elkind, Whitmore and Alescio[13]. The second dip in the radiosensitivity curve is recorded in published experimental results, despite the implication from the curves commonly drawn that it should not exist.

The association between control and radiosensitivity can be demonstrated in site and in biochemistry as well as in behaviour. The cytoplasm of the algae *Acetabularia* contains a sufficiently autonomous control system to maintain a rhythmic activity without a nucleus[15], and is also the site of most of the radiosensitivity of the organism. A low concentration of actinomycin D has been found to inhibit luminescence rhythms[16] and is known to reduce radio-resistance and inhibit recovery from irradiation[13]. Since actinomycin is believed to act specifically by the inhibition of *m*RNA synthesis, these results implicate *m*RNA in both rhythmic control and radiosensitivity. Irradiation also causes a phase shift in cells, indicated by a lengthening of the synthetic period[17]. Harker[18] has found, on a multicellular scale, that a stable phase shift of increasing magnitude is produced as the dose given is increased from 100 r. to 10,000 r. At less than 100 r. the phase did shift, but was unstable and soon reverted to its original position.

Intracellular and intercellular control systems must be closely linked, and therefore irradiation experiments which affect and indicate the phasing of the first should provide a tool for studying the second. Of theoretical interest is the possibility that this approach may provide a clue towards the formulation of fundamental temporal principles of cellular organization.

DELAYED FLUORESCENCE OF CHLOROPHYLL *IN VITRO* AND *IN VIVO*

By DR. C. A. PARKER and THELMA A. JOYCE
Royal Naval Scientific Service, Admiralty Materials Laboratory, Holton Heath, Poole, Dorset

WE have recently made measurements of the delayed fluorescence of chlorophyll, both as the pure substance in dilute solution and in the complex pigment system of living leaf cells. This article presents a summary of the results of the measurements in solution and compares them with measurements in leaves.

The spectra of prompt and delayed fluorescence of a deoxygenated 10^{-6} M solution of chlorophyll in ethanol are shown in Fig. 1 (curves 1 and 2). With high rates of light absorption at room temperature in this solvent, the intensity of delayed fluorescence was found to be approximately proportional to the square of the rate of absorption of exciting light, indicating that it was produced mainly by means of the process of triplet–triplet annihilation[1] (that is to say, it was mainly *P*-type delayed fluorescence[2]). At lower rates of light absorption there were indications that a small proportion of *E*-type delayed fluorescence[2] was also present. The lifetime of the delayed fluorescence at room temperature was 0·4 msec. For the *P*-type mechanism this would correspond to half the triplet lifetime (τ_t).

The energy of the chlorophyll triplet was determined by measurement of its delayed fluorescence in propylene glycol. The higher viscosity of this solvent reduces the rate of encounter between triplets, and, within the temperature range 20°–80° C, the intensity of *P*-type delayed fluorescence was small in comparison with that of the *E*-type delayed fluorescence. The latter is produced by thermal activation of molecules from the triplet level to the first excited singlet level[3]. From measurements of the intensity and lifetime of the delayed fluorescence as a function of temperature the activation energy was found to be 10·2 kcal per mole. The lifetime of the delayed fluorescence in propylene glycol at 21° C was 0·8 msec. For *E*-type delayed fluorescence, this should be equal to the lifetime of the triplet and it is equal to the triplet lifetime in ethanol calculated from the lifetime of *P*-type delayed fluorescence in this solvent. It agrees with the value in propylene glycol reported by Livingston and McCartin[4].

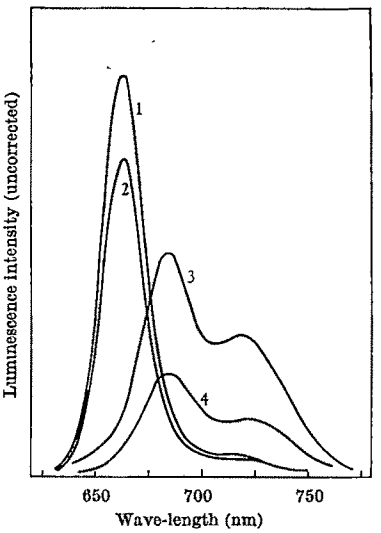

Fig. 1. Prompt and delayed fluorescence spectra. Curves 1 and 2: 10^{-6} M chlorophyll *a* in ethanol at 21° C with a rate of light absorption of 7×10^{-6} einstein $l.^{-1}$ sec^{-1} at 405 nm and band-width of 10 nm: intensity scale for delayed fluorescence (curve 2) is 2,100 times greater than that for prompt fluorescence (curve 1). Curves 3 and 4, Rhododendron leaf with incident intensity of 3×10^{-9} einstein cm^{-2} sec^{-1} at 436 nm, with band-width of 20 nm: intensity scale for delayed fluorescence (curve 4) is 500 times greater than that for prompt fluorescence (curve 3)

For the measurements of fluorescence *in vivo*, freshly plucked leaves of a variety of plants were used. Each leaf was mounted so that the beam of exciting light made an angle of about 60° with the upper surface of the leaf. The luminescence was observed from a direction at right angles to that of the beam of exciting light. Because the efficiency of prompt fluorescence from chloroplasts in living cells is small (estimated by various authors to be between 0·1 and 1 per cent[5]) the prompt fluorescence spectra had to be measured with a comparatively high instrumental sensitivity and precautions were required to prevent scattered exciting light from entering the monochromator used for measuring the emission spectra. The required wave-length of exciting light was isolated from a mercury lamp by means of a single monochromator. The beam was passed through a 2-cm depth of 10 per cent w/v $CuSO_4 \cdot 5H_2O$ in 0·1 N sulphuric acid to remove the small intensity of wave-lengths greater than 630 nm arising from scatter within the monochromator. The luminescence from the leaves was viewed through a 2-cm depth of 20 per cent w/v $Na_2Cr_2O_7 \cdot 2H_2O$ which removed all wave-lengths shorter than about 560 nm. Prompt fluorescence spectra could be measured at comparatively high resolution (3·3 nm band-width) and these spectra could be approximately corrected for the spectral sensitivity variations of the instrument[6]. To obtain sufficient light to measure the spectra of delayed fluorescence a band-width of 20 nm had to be used; because of the rapid variation of spectral sensitivity within the wave-length region of interest, correction of these spectra was not worth while.

The corrected prompt fluorescence spectra observed with a rhododendron leaf are compared in Fig. 2 with that of chlorophyll *a* in ethanolic solution. The spectrum of the leaf showed two bands at 1·46 and 1·35 μm^{-1} (685 and 741 nm) the relative intensity of which varied with the wave-length of excitation. The relative intensity of the 685-nm band was reduced considerably with excitation at 546 nm. This effect is attributed mainly to greater self-absorption caused by the greater depth of penetration of 546 nm as compared with 436 nm or 405 nm. The spectra at the latter wave-lengths are in general agreement with those reported for green leaves by other workers[5] and are probably due mainly to chlorophyll *a*. The relative intensities of the bands varied somewhat with different specimens and it is probable that the observed intensity of the 685-nm band is reduced by self-absorption even with 405- or 436-nm excitation. The prompt fluorescence spectra of the leaves from other plants showed the same two bands, although their relative intensities again varied (column 2 of Table 1).

Delayed fluorescence was observed with all types of leaf examined. Typical spectra (uncorrected and at low resolution) are shown in Fig. 1 (curves 3 and 4). Very similar results were obtained with the other types of leaf. The shapes of the delayed fluorescence spectra were always similar to those of the corresponding prompt fluorescence, whatever the wave-length used for excitation. There were pronounced transient effects, both in prompt and delayed fluorescence, on changing the level of illumination on the leaf. The spectra in Figs. 1 and 2 were obtained with steady illumination at the indicated

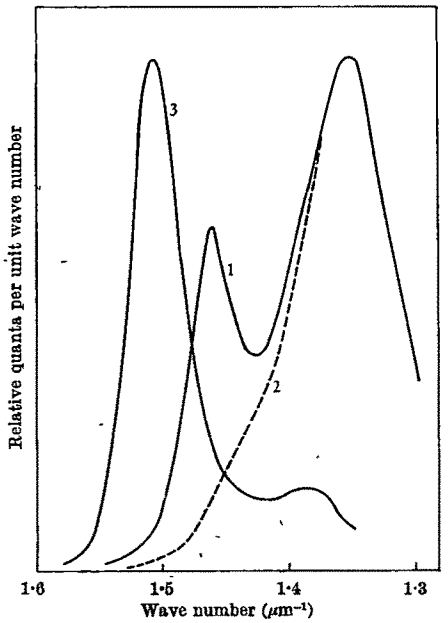

Fig. 2. Corrected prompt fluorescence spectra. Rhododendron leaf with excitation by: (1) 3×10^{-9} einstein cm^{-2} sec^{-1} at 436 nm; (2) $1{\cdot}4 \times 10^{-9}$ einstein cm^{-2} sec^{-1} at 546 nm; (3) 10^{-6} M chlorophyll *a* in ethanol. Band-width was 3·3 nm for (1), (2) and (3)

intensities. Variation in the intensity of the steady illumination produced comparatively little change in spectral shape, but this was not investigated in detail.

On switching on the illumination after a period of darkness, high initial levels of prompt and delayed fluorescence were recorded. These fell to steady values after a few minutes of irradiation. Typical results obtained with a 1-sec pen-speed recorder are shown in Fig. 3 (curves *C*–*F* full lines). The fall in intensity was greatest at the highest intensity of exciting light and the fall in the intensity of delayed fluorescence was greater than that of the prompt fluorescence. The ratio of the efficiencies of delayed to prompt fluorescence in various types of leaf after stabilization at one intensity of exciting light are given in the third column of Table 1. The values are remarkably similar and the delayed fluorescence thus seems to be a property characteristic of leaf chloroplasts in general. When the intensity of illumination was increased by a factor of ten, the ratio of the efficiencies of delayed and prompt fluorescence decreased by a factor of about two. This range of intensities of illumination overlaps that in which photosynthesis becomes saturated and the prompt fluorescence efficiency increases[5].

The period immediately after the start of illumination was investigated separately, using an oscilloscope to record the transient effects (Fig. 3, curves *A* and *B*). The intensity of delayed fluorescence (in normal air) always showed the maximum between 1 and 2 sec (curve *B*). It is obvious that both prompt and delayed fluorescence are affected by more than one process occurring in the illuminated leaves. One such process is no doubt the re-orientation of chloroplasts on illumination[5] (phototaxis), although this cannot be the sole cause since prompt and delayed fluorescence are not affected in the same way.

The rates of decay of the delayed fluorescence were observed with the use of pairs of rotating sectors, synchronously driven at a frequency appropriate to the life-

Table 1. EMISSION FROM VARIOUS TYPES OF GREEN LEAF

Plant	Ratio of corrected prompt fluorescence intensity at 685 nm and 741 nm	Ratio of delayed to prompt fluorescence intensity with steady illumination $\times 10^2$
Rhododendron	0·68	1·3
Silver birch	0·81	1·1
Rose bush	0·90	1·3
Lupin	0·72	1·6
Fern	0·77	1·5
Grass	0·82	1·5

Intensity of illumination was 3×10^{-9} einstein cm^{-2} sec^{-1} at 436 nm.

Table 2. RHODODENDRON LEAVES

Atmosphere	Approximate intensity of exciting light (einstein cm^{-2} sec^{-1})	Period of measurement (msec)	Lifetime of delayed fluorescence: Mean lifetime (msec)
Normal air	$\sim 10^{-7}$	0–1	2·4
			2·8
			2·9
			2·9
Normal air	$\sim 10^{-7}$	10–15	27
Normal air	$\sim 10^{-7}$	100–150	>100
Normal air	$\sim 10^{-8}$	0–1	3·6
Air + 40 per cent carbon dioxide	$\sim 10^{-8}$	0–1	5·9

time to be observed[6]. The decay was non-exponential (see Fig. 4). Some mean lifetimes calculated from the mean slopes of the log-plots over the indicated periods of time are shown in Table 2. The fastest rates of decay (taken over the period 0–1 msec) corresponded to lifetimes of 2–3 msec. Later, in the course of the luminescence decay, much greater lifetimes were observed although the intensities were very low.

Change in the water content of the surrounding atmosphere from about 50 per cent to 100 per cent relative humidity, or change in the oxygen content from 20 per cent to 100 per cent, produced only small changes in the intensities of prompt and delayed fluorescence. In comparison, the effects produced by changing the carbon dioxide content of the air were quite pronounced (Fig. 5). Small concentrations (0·03 per cent) appear to quench the

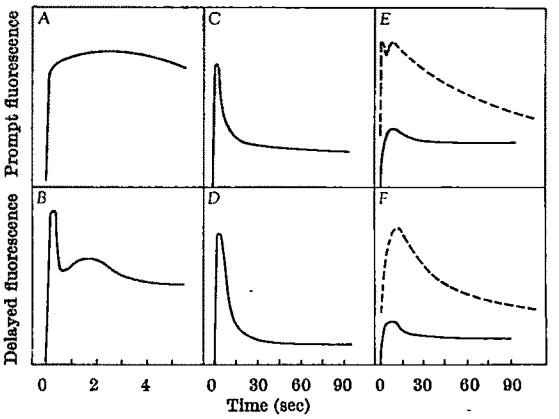

Fig. 3. Transient effects with rhododendron leaves after a period of darkness. Full lines refer to normal air, pecked lines to 40 per cent carbon dioxide. Intensities of illumination were: *A* and *B*, $\sim 10^{-7}$ einstein cm^{-2} sec^{-1} of 436 + 546 + 578 nm; *C* and *D*, 3×10^{-8} einstein cm^{-2} sec^{-1} of 405 nm; *E* and *F* full lines, 3×10^{-9} einstein cm^{-2} sec^{-1} of 405 nm; *E* and *F* dashed lines, 3×10^{-9} einstein cm^{-2} sec^{-1} of 436 nm. Intensity scales for different curves are not comparable

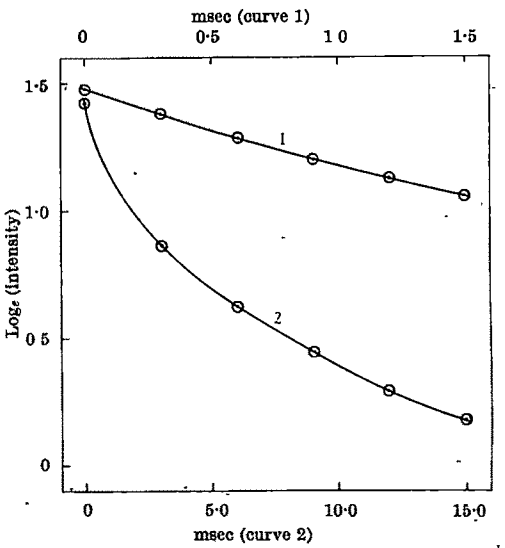

Fig. 4. Decay of delayed fluorescence of rhododendron leaves after switching off illumination. Curve (1) (upper time scale) with 100 c/s sectors. Curve 2 (lower time scale) with 25 c/s sectors

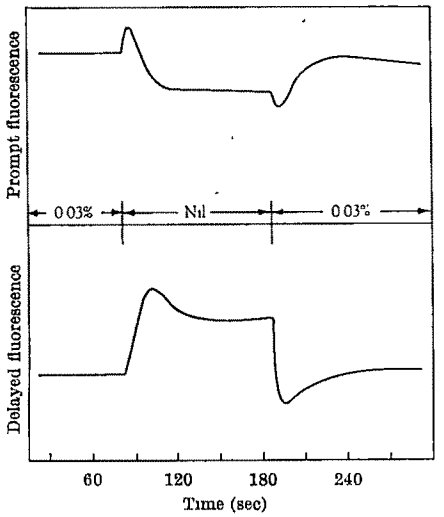

Fig. 5. Effect of low concentration of carbon dioxide. Air saturated with water vapour at 22° C and containing the indicated concentration of carbon dioxide was passed over the rhododendron leaf while it was illuminated with an intensity of 3×10^{-3} einstein cm^{-2} sec^{-1} of 436 nm

delayed fluorescence. The effects are related to, although not the same as, the changes in prompt fluorescence. The effect of high carbon dioxide concentrations is quite different. After a period of darkness in an atmosphere containing about 40 per cent of carbon dioxide, illumination produced an initial intensity of delayed fluorescence several times greater than that observed in normal air. The intensity then slowly fell (Fig. 3, dashed lines) and after some minutes attained a level similar to that in normal air. The initial increase in intensity was accompanied by an increase in the lifetime (Table 2).

It is clear that the delayed fluorescence of chloroplasts is affected in a variety of ways by the complex processes occurring in the living cell. It would be premature to attempt a discussion of the present limited observations in terms of present-day theories about the nature of the primary processes of photosynthesis, for example, their relationship to the two pigment systems described by Duysens[7]. However, some general observations about the possible origin of the delayed emission are called for. At least two kinds of mechanism have to be considered, namely: (1) *P*-type of *E*-type delayed fluorescence arising from chlorophyll triplets; (2) chemiluminescence arising either from recombination of the primary products of photo-reaction of chlorophyll itself, or from the interaction of chlorophyll with some energy-rich products of the photosynthetic reaction. We shall discuss only mechanisms of the first kind. Bertsch, who observed delayed fluorescence from *Chlorella*[8], attributed it to a back reaction following chlorophyll reduction, that is, to a mechanism of the second kind.

The fact that in fluid solution the chlorophyll triplet is strongly quenched by exceedingly low concentrations of molecular oxygen might at first sight suggest that the triplet lifetime in the living cell would be very small. However, the chlorophyll in chloroplasts is in a highly organized state and the situation may in some respects be analogous to that of concentrated solutions in rigid glasses where the degree of vibrational and rotational freedom is reduced and the triplets are shielded from collisional quenching by the high viscosity. Indeed, the non-exponential decay of the delayed fluorescence and its intensity relative to that of the prompt fluorescence are both reminiscent of the effects observed with phenanthrene in rigid media at low temperature[9]. These effects were explained in terms of triplet–triplet annihilation with the establishment of a non-random distribution of triplet molecules. In such a system the observed initial rate of decay of delayed fluorescence is considerably greater than the rate of decay of the mean triplet concentration. Applied to chloroplasts it would require the triplet lifetime of chlorophyll to be greater than 100 msec, that is, considerably greater than that observed in solution even at low temperature.

The following alternative involves the emission of *E*-type delayed fluorescence and does not require the chlorophyll triplet to have such a long lifetime. It is now generally accepted that the transfer of both singlet and triplet energy could readily occur within the chloroplast[10] so that the absorbed energy is ultimately transported to the chemically reactive centres in the photosynthetic unit. It might then be supposed that at these centres both kinds of energy are degraded to a triplet level having a much longer lifetime, and thus a better chance of encountering a substrate molecule. Reaction with substrate would result in quenching of these triplets and the non-exponential decay of delayed fluorescence could simply be a reflexion of the presence of a variety of reaction centres having different degrees of accessibility to the substrate. The reactive centre could be a molecule other than chlorophyll provided that its triplet level was sufficiently close to allow a small degree of re-population of the excited singlet levels of adjacent chlorophyll molecules by thermal activation. The observed quenched lifetimes would then correspond not to the triplet state of chlorophyll, but to the triplet state of the molecules at the reaction centres. With such a mechanism the delayed fluorescence would be directly related to a primary photosynthetic act, and would not, as Bertsch[8] suggested, be merely a result of the imperfect operation of the photosynthetic machinery.

EFFECT OF DESASPIDIN ON PHOTOSYNTHETIC PHOSPHORYLATION AND RELATED PROCESSES

By GEOFFREY HIND

Department of Biology, Brookhaven National Laboratory, Upton, New York

THE uncoupling of oxidative phosphorylation by desaspidin and related phlorobutyrophenone derivatives was described in 1962 by Runeberg, who later showed that these substances also affect myosin ATPase[1] and the latent mitochondrial ATPase[2].

Baltscheffsky and de Kiewiet[3] investigated the activity of desaspidin in photophosphorylation by isolated chloroplasts. They found that the phosphorylations accompanying cyclic electron flow catalysed by two different redox agents, phenazine methosulphate (PMS) and

dichlorophenol-indophenol (DCPI), were as sensitive to desaspidin as was oxidative phosphorylation in mitochondria. The lack of net electron flux did not permit recognition of this inhibition specifically as an uncoupling effect, although this was inferred.

It is convenient to recall at this point that much of the electron transport pathway in photophosphorylation with artificial cofactors, or with the natural system reducing NADP from water, is unknown. Consequently the location and number of energy-coupling sites remain to be elucidated. A major step was taken in solving a comparable problem in the phosphorylating apparatus of bacterial chromatophores when Baltscheffsky *et al.*[4] found that the antibiotic valinomycin (an uncoupler of oxidative phosphorylation) partially inhibited synthesis in a 'physiological' electron flow system, but did not affect photosynthetic phosphorylation involving a cyclic electron flow sequence promoted by PMS. This led to the recognition of two coupling sites and their appropriate locations in *Rhodospirillum rubrum* photophosphorylation. Valinomycin proved to be rather ineffective with plant chloroplast systems, but the hope was maintained that some other selective inhibitor might be found which would also allow a definitive recognition of plural coupling sites in this case. Desaspidin appeared to be such a compound, for when Baltscheffsky tested the activity of low concentrations in non-cyclic electron flow systems involving NADP, FMN or ferricyanide reduction, the associated ATP synthesis was unaffected[3]. Hundred-fold higher concentrations were required to inhibit these systems compared with the PMS and DCPI cyclic processes mentioned earlier.

These findings were amplified in Arnon's laboratory[5,6] and led to the proposition that not only are there three coupling sites, but more notably that the transfer of an electron from water to NADP is driven by a single red light quantum. While studying the effects of desaspidin on photo-induced light-scattering changes in isolated spinach chloroplasts, the author observed lag phenomena suggesting photo-destruction of the inhibitor. This paper attempts to show that perhaps all the differential sensitivity exhibited by the various chloroplast systems to desaspidin may reflect nothing more than the relative stabilities of this compound under the various reaction conditions.

Uncoupling by desaspidin. Both Baltscheffsky and Arnon assert as evidence for uncoupling activity that desaspidin inhibits ATP synthesis but not electron flow during the photo-reduction of NADP using reduced DCPI as electron donor. Phosphorylation in this system is, however, thought to be cyclic, and not correlated with the NADP reduction rate[7–9].

The ability of almost all uncoupling treatments to increase the rate of decay of X_E (a possible non-phosphorylated intermediate of photophosphorylation[10,11]) can be used to test for uncoupling of a cyclic system, not otherwise possible. Table 1 shows that roughly 0·5 μM desaspidin is needed to half-inhibit X_E accumulation catalysed by pyocyanine in air. As the concentration is increased, the ATP yield and the X_E half-life decrease, strongly indicating an uncoupling effect of desaspidin.

Effect of light-scattering changes. Photo-dependent light-scattering changes have been classified into three general types[11]: (1) a low amplitude, dark-reversible increase in scattering (chloroplast shrinkage) observed at *p*H values close to 6·0; (2) a high amplitude, dark-reversible increase induced by illumination in the presence of chlorpromazine (CPZ), and almost independent of *p*H; and (3) an irreversible decrease in scattering associated with vacuolation and induced by illumination with amines or ammonia. Table 2 presents the effects of desaspidin on the foregoing processes, using pyocyanine as the catalytic cofactor. Its effect on chloroplasts illuminated alone at *p*H 8·0 is also studied (line 3) to check whether desaspidin itself can promote shrinkage or swelling. This proved not to be the case, and desaspidin inhibited in all four systems, resembling in this respect the carbonyl cyanide phenylhydrazone uncouplers (CCPs) (ref. 12). The greater resistance of the swelling at *p*H 8 to desaspidin is noteworthy: 1·0 μM inhibits ammonia swelling by 45 per cent, and *p*H 6·2 contraction by 86 per cent (without CPZ) or 94 per cent (with CPZ). Desaspidin, especially with CPZ, appeared to inhibit the 'on' response significantly more than could be attributed to its enhancement of the competing reversion rate. This behaviour simulates an inhibition of electron flow rate but, as will be shown, is not so caused.

Table 1. EFFECT OF DESASPIDIN ON X_E

	X_E decay, $t_{0.5}$ (sec)	ATP yield (mμmoles/mg chlorophyll)

Reaction conditions as for Table 1 but with chlorophyll 25 μg/ml. Sample absorbance measured with Cary 'Model 14' Spectrophotometer as previously described (ref. 11).
* CPZ; chlorpromazine.

Release from desaspidin inhibition. According to the postulates of Baltscheffsky and of Gromet-Elhanan and Arnon, it should be possible to restore scattering changes to the inhibited systems of Table 2 on addition of a cofactor of non-cyclic electron flow such as ferricyanide. Ferricyanide prevents cyclic phosphorylation[13] and would allow electron flow through the desaspidin-insensitive 'second' coupling site. Fig. 1 shows the inhibition of ammonia-induced swelling by desaspidin with pyocyanine as cofactor (curves 1 and 2). Adding ferricyanide gives rapid release from the inhibition and swelling rate becomes that of the control with ferricyanide plus pyocyanine without desaspidin (omitted for clarity from Fig. 1). Curve 3 demonstrates that the released system is still sensitive to CCP inhibition.

Table 3 summarizes similar curves showing the release by ferricyanide of the desaspidin-inhibited *p*H 6·2 low amplitude contraction. The inhibition falls from 95 per cent with pyocyanine alone to 25 per cent on adding ferricyanide. However, the 'on' response after adding ferricyanide was here much slower than the control and and was preceded by a long lag.

Table 3. LIGHT-SCATTERING CHANGES DRIVEN FROM TWO APPARENT SITES

Reaction conditions as for Table 1.
* Curve extrapolated to exclude initial lag period of about 20 sec.

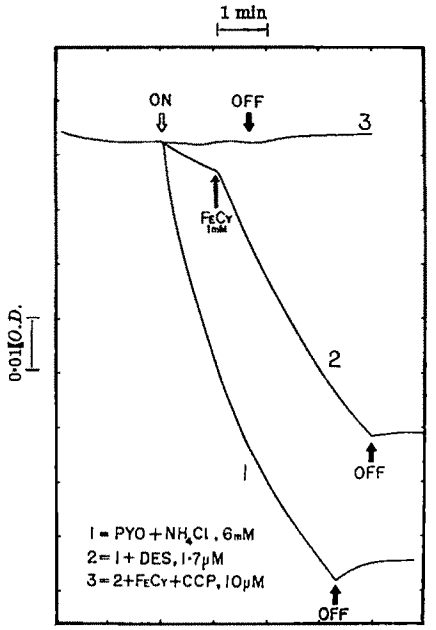

Fig. 1. Inhibition of chloroplast swelling by desaspidin. Ferricyanide added to cuvette at arrow (curve 2). Reaction conditions as for Table 2

Investigation of the lag period revealed several disturbing features, namely: (1) the lag was only present the first time a sample was illuminated—subsequent 'on' and 'off' sequences essentially resembled the control system with no desaspidin, both in the absence of lag and in their rapid 'on' response; (2) a lag was reintroduced by adding desaspidin to a sample already illuminated sufficiently to overcome the lag from an initial addition of the inhibitor; (3) the total duration of the lag was the same whether illumination was continuous or split into flashes of 5 sec separated by dark intervals of 2 min; and (4) the lag duration was roughly proportional to the desaspidin concentration at levels many times greater than needed to inhibit completely the pyocyanine-catalysed system. Table 4 illustrates some of these data.

Table 4. Concentration Dependence of Lag Duration

μM DES	0	0·7	1·5	3	7·5
Max. 'on' rate ΔA/min	0·20	0·12	0·10	0·08	0·05
Initial lag (sec)	3	11	18	23	56
Corrected lag	0	8	15	20	53
Corrected lag/μM DES	—	11·4	10·0	6·7	7·1

Reaction medium contained *tricine* 0·01 M, sodium chloride 0·02 M, dimethylglutarate 2·5 mM, potassium ferricyanide 1 mM, chlorophyll 20 μg/mL, and desaspidin as indicated above. All data refer to the first illumination period of each sample.

The evidence led to the suggestion that desaspidin might be removed or destroyed during the lag period. This latter was confirmed when it was shown that the lag period was decreased by pre-illuminating a sample with colloidal chlorophyll and ferricyanide before adding the chloroplasts (Table 5).

Table 5. Photosensitized Destruction of Desaspidin

μg/ml. colloidal chlorophyll	1·2	1·2	2·4
Minutes pre-illumination	0	10	10
Max. 'on' rate ΔA/min	0·029	0·025	0·016
Lag (sec)	35	18	6

Reaction mixture as for Table 4, with 3 μM desaspidin, except that chloroplasts were added only after the above pre-illumination in the presence of colloidal chlorophyll. Chlorophyll was extracted and adsorbed on sucrose by the method of Vernon (ref. 14) and added as an aqueous suspension. All data refer to the first illumination period. Both pre-illumination with chlorophyll and illumination with chloroplasts were conducted in red light at 5° C and *p*H 6·2.

In another type of experiment, chloroplasts and pyocyanine were illuminated without and then with added desaspidin (Table 6, columns 1 and 2). The inhibition of light scattering was then released by illumination with ferricyanide (Table 6, columns 3*a* and 3*b*). At this point addition of ascorbate sufficient to reduce all the ferricyanide did not restore the expected desaspidin-sensitive pyocyanine-catalysed system, but gave a released response (column 4) sensitive, none the less, to fresh addition of desaspidin. The addition of ascorbate (column 4) actually improved the maximal rate of scattering change (see column 3*b*). The control in column 5 shows that adding ferricyanide and excess ascorbate did not affect the scattering changes greatly (see column 1) and did not confer insensitivity to desaspidin (column 6).

Table 6. Inactivation of Desaspidin by Ferricyanide

Column System	1 Control	2 +DES	3*a* +Ferri-cyanide	3*b*	4 +Asc	5 +Ferri-cyanide +asc	6 +Ferri-cyanide +DES +asc
Extent, ΔA	0·068	0·023	0·054	0·060	0·053	0·058	0·018
Max. rate ΔA/min	0·312	0·007	0·038	0·108	0·219	0·348	0·006
Lag (sec)	0	1	42	1	0	0	7

Columns 1–4 represent successive treatments of the same sample. After adding ferricyanide, two successive scattering responses (3*a*, 3*b*) were studied. Reaction mixture contained *tricine* 0·01 M, sodium chloride 0·02 M, dimethylglutarate 2·5 mM, pyocyanine 25 μM, and where indicated: potassium ferricyanide 0·3 mM, sodium ascorbate (asc) 1 mM, and desaspidin 3 μM. Chlorophyll 20 μg/ml., *p*H 6·2.

The foregoing data show that the sensitivity of the pyocyanine-catalysed responses varies with the prior history of the desaspidin. We are observing, therefore, not the differential uncoupling of chloroplast reactions by desaspidin, but the differential destruction of desaspidin by chloroplast systems.

Effect of desaspidin on electron transport. Fig. 2 shows the variation in electron flow rate during the first illumination of a sample containing desaspidin and ferricyanide. The rate declines steadily to about 25 per cent of its initial value and remains at this lower level throughout subsequent illumination periods. Light-scattering measurements show that the lag during the first illumination period is roughly coincident with the high initial ferricyanide reduction rate, and correspondingly, the second 'on' and 'off' sequence with low initial electron flux is free of light-scattering lag. Both curves are interpreted as indicating that desaspidin, an uncoupler of the type inhibitory to light-scattering changes, is destroyed during illumination with ferricyanide.

Fig. 3 was obtained with the same chloroplast preparation. Here the electron transfer was fully uncoupled with

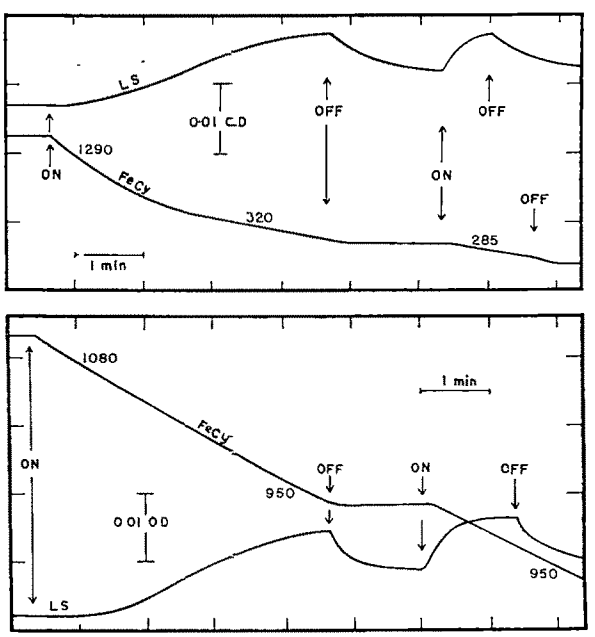

Fig. 2 (above) and Fig. 3 (below) Correlation of ferricyanide reduction at 420 mμ with light-scattering (LS) changes. Numbers refer to reduction rate in μmoles/mg chlorophyll/h. CPZ 90 μM, potassium ferricyanide 1 mM, *p*H 6·2

CPZ, the rate of 1,080 μmoles/h/mg being close to that of 1,290 μmoles seen at the start of the first illumination in Fig. 2. The rate did not decline during illumination in this case. Nonetheless, a lag in the 'on' response of the initial light-scattering curve was still present. These data show that the effect of desaspidin on turbidity changes is not specifically related to an effect on electron flux.

pH dependence of lag. It will be appreciated from Fig. 1 that the release of desaspidin-inhibited swelling by ferricyanide is virtually immediate. Yet we have seen in the foregoing section that both low and high amplitude contractions are released only after a substantial lag.

Since the swelling reaction is studied at *p*H 8 and the contractions at *p*H 6·2, the possibility arises that the *p*H condition determines whether a lag will be observed. Therefore, the CPZ-induced high amplitude contraction was studied at both these *p*H values with the uncoupler concentration adjusted for each *p*H to provide identical electron flow rates. The 'on' and 'off' turbidity responses were similar at high and low *p*H values. Adding desaspidin did not affect the electron flow rates, but did induce lag in the first contraction cycle at *p*H 6·2 (Table 7). There was no corresponding induction of lag at *p*H 8·0.

Table 7. *p*H DEPENDENCE OF LIGHT-SCATTERING 'ON' RESPONSE WITH FERRICYANIDE AS OXIDANT

*p*H	6·2	6·2	8 0	8 0
μM DES	0	5	0	5
Extent, ΔA	0·15	0 11	0·13	0·07
$t_{0.5}$ (sec)	43	80	30	56
Lag (sec)	0	30	0	2

Reaction conditions as for Table 4, with addition of CPZ 75 μM (*p*H 6·2) or 50 μM (*p*H 8 0). Electron flow rate 900 μmoles ferricyanide/mg chlorophyll/h.

Considering the phenolic nature of desaspidin and the data of Table 7 and Fig. 1, it seems reasonable to propose that at alkaline *p*H the destruction of desaspidin in an oxidizing medium is so rapid as to give an immeasurably brief lag period in light-scattering changes. One might further predict that in oxidizing media the time-course of photophosphorylation at *p*H 8·0 would be free of detectable lag. This proved to be the case.

Desaspidin activity with FMN as cofactor. Both the Stockholm and the Berkeley groups[3,5] have shown that non-cyclic photophosphorylation with FMN as cofactor is insensitive to desaspidin uncoupling. FMN is not in itself a strong oxidant akin to ferricyanide, and so the necessary conditions for making the FMN phosphorylation system patent to desaspidin are of special interest to our interpretation.

The first such condition is apparently an alkaline *p*H. Table 8 shows that light-scattering changes at *p*H 8·0 show an initial lag of 41 sec (see Table 7), but quickly recover and attain high maximum initial rates. At *p*H 6·2 the extrapolated lag is longer and the initial rate improves only slightly between illumination sequences. Table 8 also presents data for a system catalysed by PMS. In this case the desaspidin appears to be stable for there are no obvious lag periods. The maximum initial rates are close to the minimum initial rates seen with FMN: inhibition is much more severe.

Our interpretation of the foregoing data is that FMN-catalysed systems, perhaps by generating hydrogen peroxide, are capable of destroying desaspidin fairly rapidly at *p*H 8·0. However, the presence of a lag even at *p*H 8·0 suggests that in a phosphorylation run the time of assay will be critical in determining the percentage inhibition. Gromet-Elhanan and Arnon used 10-min

Table 8. *p*H DEPENDENCE OF LIGHT-SCATTERING 'ON' RESPONSE WITH FMN OR PMS AS COFACTOR

Cofactor	FMN				PMS			
*p*H	8 0	8 0	6·2	6 2	8·0	8·0	6·2	6 2

* mμmoles ATP yield. *Tricine* 0 01 M, sodium chloride 0·02 M, ADP 1 5 μmoles, magnesium chloride 5 μmoles, sodium phosphate-^{32}P 10 μmoles, FMN 17 μM. Volume 2·5 ml. Red light, 5° C, *p*H 8·0. Gas phase: air.

illumination periods and found no desaspidin sensitivity with FMN as cofactor. What is the sensitivity of the same system in brief time-courses?

Table 9 shows time-courses with and without desaspidin for phosphorylation catalysed by FMN. The percentage inhibition is 100 for the first minute and gradually falls to 30 per cent at 20 min. With slightly less uncoupler and longer incubations it has proved possible to pass from almost complete inhibition to full activity.

Before examining further the time-dependence of inhibition it is necessary to refer to Fig. 4. FMN-catalysed photophosphorylation conducted in evacuated Thunberg tubes is completely inhibited by 1·3 μM desaspidin and remains so during illumination for 10 min. Admitting air after 4 min allows phosphorylation to begin. It is not known whether the oxidant removed by evacuation is oxygen or hydrogen peroxide. Peroxide is formed by aerobic or anaerobic FMN reduction thus:

$$\text{FMN} + \text{H}_2\text{O} \xrightarrow{\text{chl.hv}} \text{FMNH}_2 + 1/2\,\text{O}_2$$
$$\text{FMNH}_2 + \text{O}_2 \longrightarrow \text{FMN} + \text{H}_2\text{O}_2$$

FMN reduction rates. Anaerobic FMN reduction rates can be measured by following the decline in FMN absorbance at 450 mμ. It is then found that enhanced reduction rates are detectable with as little as 0·09 μM desaspidin. Fig. 5 shows concentration curves for this effect of desaspidin on FMN reduction rates.

Fig. 5 also shows curves for the inhibition of photophosphorylation with FMN or PMS as cofactors, and with long and short illumination periods. In confirmation of Table 9 the FMN tubes assayed after 10 min of light showed roughly a ten-fold decrease in sensitivity to desaspidin. However, the 50 per cent uncoupling points as measured from (i) anaerobic FMN reduction rates, (ii) brief time-courses of FMN-catalysed photophosphorylation, and (iii) PMS-catalysed photophosphorylation are very similar, lying between 0·1 and 0·2 μM. Inhibition of electron flow by high desaspidin concentrations was confirmed[3].

Ferredoxin-catalysed reactions. Arnon *et al.*[6] present data for the effect of desaspidin on anaerobic ferredoxin-catalysed cyclic and non-cyclic photophosphorylation. The cyclic system, with CMU present to inhibit oxygen evolution, was half-uncoupled by about 0·2 μM desaspidin. In contrast, 3 μM desaspidin was required for the same

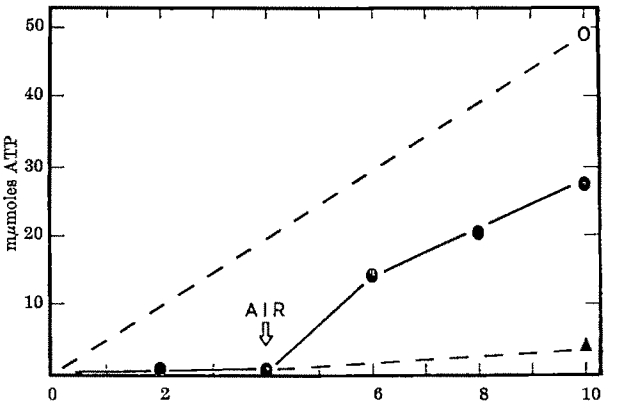

Fig. 4. Inhibition of FMN-catalysed anaerobic phosphorylation by 1 3 μM desaspidin. ○, Evacuated then shaken with air before illumination; ▲, anaerobic throughout; ●, aerated after 4 min anaerobic illumination. FMN 170 μM, other reaction conditions as for Table 9

effect on ATP synthesis accompanying the non-cyclic reduction of NADP in the absence of CMU.

The data for NADP reduction in the same paper suggest that the rate is scarcely affected by desaspidin below 5 μM. However, it is common to find such a result when electron flow is already enhanced by the coupling reagents[15].

Fig. 6 confirms that phosphorylation accompanying NADP reduction is less than 50 per cent inhibited by 1 μM desaspidin during a 10-min illumination period. Over a shorter time-course, however, 0·1 μM desaspidin gives half-inhibition. The situation is thus similar to that described for FMN (Fig. 5). A point of difference arises with the electron flow rates: FMN reduction rates measured anaerobically at *p*H 8 are enhanced by desaspidin, NADP reduction rates followed aerobically at *p*H 8 are not. Light-scattering studies have shown that during aerobic illumination at *p*H 8·0 with ferredoxin and NADP, high-amplitude contraction soon recovers from desaspidin inhibition, but does not do so at *p*H 6·2. Under the assumption that the NADP system destroys desaspidin rapidly at *p*H 8·0 but much less so at *p*H 6·2, the effect of desaspidin on NADP reduction at low *p*H was investigated. The result presented in Fig. 6 affirms that NADP reduction is 50 per cent enhanced by less than 0·2 μM desaspidin under conditions of desaspidin stability.

Evidence has been presented for the lability of desaspidin under alkaline conditions and in oxidizing media. It is noteworthy that even during storage in 60 per cent ethanol at 3° C, desaspidin gradually loses potency so that fresh solutions must be prepared every 7–14 days. The breakdown products appear to be inactive as uncouplers of photophosphorylation, but may act as inhibitors of electron flow. Their composition is being determined.

Photosynthetic reactions are studied in the presence of three broad categories of redox environment. The first category includes more or less oxidizing conditions due to the presence of an oxidant such as ferricyanide, manganese dioxide, or hydrogen peroxide. In long time-courses these media appear to support desaspidin-insensitive photophosphorylation as a result of photo-oxidation of the uncoupler.

The second class comprises reducing situations created by ascorbate or anaerobicity. In these media one finds the true susceptibility of photophosphorylation to desaspidin which gives 50 per cent uncoupling around 0·2 μM. Runeberg found that oxidative phosphorylation was not affected at this concentration and required 1·0 μM desaspidin for half-uncoupling[16].

In the third category lie cofactors having mid-point potentials close to zero which can support desaspidin-sensitive photophosphorylation, as with pyocyanine; or an apparently partially sensitive reaction as found with PMS. Gromet-Elhanan and Arnon found the PMS system to be 70 per cent inhibited in argon and 35 per cent inhibited in air, using 0·5 μM desaspidin (cf. Fig. 5). They could not explain this result since, even in air, PMS is well documented as catalysing a cyclic electron flow. Our interpretation is that, as shown for the FMN system, the destruction of desaspidin requires oxygen. It is probable that variability in the natural ascorbate level of spinach chloroplast suspensions may also affect the apparent susceptibility of PMS-catalysed phosphorylation.

Fig. 5. The cause of desaspidin destruction during anaerobic electron transfer from water to NADP by way of ferredoxin[6] is unknown. Possibly ferredoxin, which is unstable in illuminated chloroplast preparations[17], liberates ferric ion which in turn oxidizes the uncoupler. Using 3 mg ferredoxin per sample and 0·5 μM desaspidin[6], only 0·2 per cent of the iron protein need release Fe^{+++} for the desaspidin to be so oxidized (assuming 1 : 1 stoichiometry for the desaspidin/Fe^{+-+} interaction). Such a mechanism would also account for the lack of desaspidin destruction in the highly sensitive NADP reduction system using ascorbate as electron donor[3].

Our demonstration of aerobic desaspidin-sensitive NADP reduction makes totally unnecessary the proposed phosphorylation site close to the splitting of water, and the ensuing revision of the electron transfer pathway[6].

Comparable effects of desaspidin to the CCP derivatives in inhibiting the scattering responses induced by other uncoupling agents suggest that desaspidin may also occupy a place at the top of the 'uncoupler hierarchy'[12]. Discrimination between two coupling sites by CCP has also been proposed[15]. Avron observed that in this case the cyclic systems appeared to be less sensitive than the non-cyclic. It was also found that the severity of CCP uncoupling increased markedly as the light intensity was lowered. The general criticism may be raised that conditions producing a change in the steady-state level of the redox carriers close to the coupling site (for example, light intensity and added cofactor) might be expected to modify the susceptibility of photophosphorylation to those uncouplers acting closest to electron transport and possibly with the redox components themselves.

There seems to be no concrete evidence for plural coupling sites in higher plant chloroplasts. Even if slight differences in the desaspidin sensitivities of phosphorylation do exist with alternative electron flow patterns, any conclusions will be subject to the same doubts as were voiced earlier with regard to CCP.

The misinterpretations caused by the lability of desaspidin illustrate that the best uncoupling agents, meaning

those to which photophosphorylation is most sensitive, are probably the worst from the point of view of reliability. Extra vigilance should be exercised in their employment with so reactive a system as the chloroplast photosynthetic apparatus. Perhaps we should re-examine the instances in which photosynthetic energy transduction has been thought to differ from that in the mitochondrion on the basis of its insensitivity to certain potent uncouplers and inhibitors of oxidative phosphorylation.

This research was carried out at Brookhaven National Laboratory under the auspices of the U.S. Atomic Energy Commission. I thank Judith Scheppele and Elaine Beebe for skilful technical assistance. A gift of desaspidin from Dr. H. Baltscheffsky is gratefully acknowledged.

REACTION KINETIC STUDIES OF THE ANTIGEN–ANTIBODY REACTION

By PROF. ROBERT P. TENGERDY and WILLIAM H. SMALL

Endocrine Section, Department of Chemistry, and the Department of Pathology and Microbiology, Colorado State University, Fort Collins

THE primary reaction between a soluble protein antigen (Ag)* and its antibody (Ab) can be followed by physical techniques such as light scattering[1,2], fluorescence polarization[3] or fluorescence quenching[4], or by chemical techniques as the equilibrium dialysis[5] or the Farr test[6,7]. Most of these techniques are applicable only for special Ag and Ab systems. Light scattering, on the other hand, could be applied for a great variety of soluble Ag–Ab systems. The measurement of light scatter in an antigen–antibody reaction gives direct information on the rate of the reaction, which depends on the combining properties of the Ag and Ab. Reaction kinetic data, obtained by light transmittance measurements, were used earlier to determine the association constant of an Ag–Ab system[8].

In the investigation reported here we attempted to obtain information on the rate of the formation of antigen–antibody complexes by comparing light scatter measurements with fluorescence quenching and saturated ammonium sulphate (SAS) precipitation measurements in the fluorescein-labelled conalbumin–anti-fluorescein-labelled conalbumin system and in the conalbumin–anticonalbumin system.

The conalbumin (CA) was a five-times crystallized preparation of about 95 per cent purity (Sigma Chemical Co.). The fluorescein isothiocyanate (FITC) adsorbed on 'Celite' (about 10 per cent FITC content) was obtained from Calbiochem. Fluorescein-labelled CA (FCA) was prepared by a technique described earlier[9]. The molar degree of conjugation of the 'Sephadex *G*-25' purified preparation was 1·92 (moles sodium fluorescein per mole CA), with a molar fluorescence quenching of 79 per cent and an apparent dissociation constant: $Ka = 4{\cdot}5 \times 10^{-12}$ (M sodium fluorescein)[9]. Iodine-125-labelled CA (ICA) was prepared according to the method of Talmage *et al.*[10]. The activity of the preparation was $5{\cdot}4 \times 10^8$ c.p.m. μg (ICA) at the beginning of the experiment. Anti-CA (ACA) and anti-FCA (AFCA) were prepared by injecting cows weighing 600–700 kg with 80 mg CA or FCA in Freund's complete adjuvant in two successive injections separated by a 2-week interval. A booster shot of 40 mg CA or FCA was given 3 weeks after the second injection. Blood was collected on the fifth day after the last injection. The Ab content of the AFCA was 4·6 per cent of the total serum protein, that of ACA was 0·9 per cent by the quantitative precipitin test. Quantitative precipitin tests were performed according to the method described by Kabat and Mayer[5].

Light scatter was measured in an Aminco Bowman spectrophotofluorometer at 90° angle using a 1-cm rectangular quartz cuvette. The incident beam was of 334 mμ and the scattered beam was of 668 mμ (secondary scatter). In the 320–350 mμ region the output of the xenon lamp was relatively high and changed little with the wave-length. By using the secondary light scatter the interference by the self-absorption of the reactants could be largely avoided. The light intensity of the scattered beam was directly recorded on a Lead and Northrup linear recorder with a 3 in./min chart speed. All measurements were made at room temperature (21°–22° C).

Fluorescence quenching was measured in the same instrument and cuvette as the light scatter at the 485 mμ excitation and 519 mμ emission peaks of the FITC (uncorrected, as found in this instrument).

All reagents and diluents were filtered through a 0·45μ pore size 'Millipore' filter before the light scatter measurements. If the reagents were kept carefully capped after filtration, low-background scatters were observed for several hours. The Ab solutions were diluted with 400 times diluted normal bovine serum (NBS) in 0·1 M borate buffer, *p*H 8·2. The use of NBS assured a relatively standard protein level in the reaction mixtures and gave a standard scatter background.

The antisera were diluted to give a uniform 0·146 mg/ml. Ab concentration in the light scatter titrations. This Ab working solution is called 'Ab-W' throughout this article. The Ag was diluted in 0·1 M borate buffer, *p*H 8·2. The borate buffer at this relatively high *p*H assured a good stability of both Ag and Ab. In physiological buffered saline both the Ag and Ab showed a slight increase in light scatter when standing at room temperature.

In the light scatter titration 1·0 ml. Ab-W was mixed with 0·1 ml. of Ag of various concentrations. The mixing was rapidly done in the quartz cuvette in 3–5 sec and recording started immediately. The same procedure was followed for fluorescence quenching measurement.

The amount of Ag bound to Ab in the form of soluble Ag–Ab complexes during the course of the immunoreaction was determined from the amount of labelled antigen precipitated by 50 per cent saturated ammonium sulphate (50 per cent SAS), essentially the same way as described in the Farr test[6]. A 1·0 ml. portion of the reaction mixture, containing ICA or FCA and AFCA, was withdrawn into a test-tube, containing 1·0 ml. SAS, at every 10 sec

* Abbreviations used in the text: Ab, antibody; ACA, bovine anti-CA serum; AFCA, bovine anti-FCA serum; Ag, antigen; CA, conalbumin; FCA, FITC labelled CA; FITC, fluorescein isothio-cyanate; ICA, iodine-125 labelled CA; NBS, normal bovine serum; SAS, saturated ammonium sulphate.

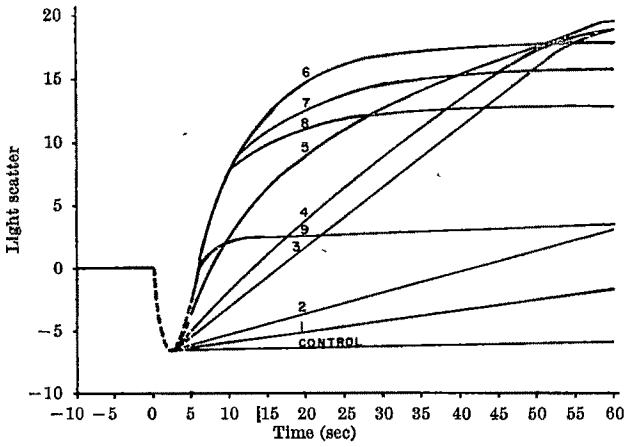

Fig. 1. The effect of antigen concentration on light scatter in the FCA–AFCA system. Protocol: 1·0 ml Ab-W (0·146 mg Ab)+0·1 ml. Ag mixed in 3–5 sec, light scatter recorded. The light scatter values are corrected for the light scatter of the control. The curves shown are redrawn from actual recorder tracings. (1), 2·0 μg FCA; (2), 5·0 μg FCA; (3), 10·0 μg FCA; (4), 15·0 μg FCA, (5), 20·0 μg FCA; (6), 25·0 μg FCA, (7), 30 μg FCA; (8), 40 μg FCA, (9), 200 μg FCA; control: 0·1 ml. borate buffer, pH 8·2. Maximum precipitation in the quantitative precipitation test was achieved when 0·020 mg FCA was added to AFCA, containing 0·146 mg Ab (Ag/Ab = 0·27 mole/mole)

after the start of the reaction. The 50 per cent SAS precipitated all soluble Ag–Ab complexes and serum globulins but not the unreacted ICA or FCA. The amount of ICA in the precipitates was determined from iodine-125 counts[11]; the amount of unreacted FCA was determined by measuring the fluorescence of the supernates by the method developed in this laboratory[12].

The reaction kinetic information obtainable from light scatter measurements is illustrated in Fig. 1 for the FCA–AFCA system. The initial reaction rate is proportional to the concentration of the Ag and the light scatter intensity increases with time in the Ab excess zone. The initial reaction rate reaches a maximum value in the slight Ag excess zone, but the value of maximum light scatter decreases in the Ag excess zone. The Ag–Ab reaction is about 90 per cent completed in 60 sec near the optimum Ag/Ab precipitation ratio, although a very slow increase in light scattering may occur over an hour period.

The rate of Ag binding by Ab in the FCA–AFCA system was followed by fluorescence quenching and by SAS precipitation, as already described. The results of this experiment are shown in Fig. 2. As can be seen, 92 per cent of the Ag was bound to Ab and precipitated by SAS 10 sec after the start of the reaction. The fluorescence quenching, which is caused by the juxtaposition of anti-FITC Ab molecules to the FCA molecule, was also practically complete in 10 sec. The data shown in Fig. 2 were taken at the optimum precipitation ratio of the FCA–AFCA system (Ag/Ab = 0·27 mole/mole); the fluorescence quenching and labelled Ag precipitation by SAS also reached maximum value within 20 sec even in the large Ab excess zone (Ag/Ab = 0·05–0·10 mole/mole). These data indicated that the primary reaction of Ag with Ab, at least in this system, occurred within seconds. The fluorescence quenching reached a maximum value in this initial phase of the reaction, and this quenching did not change in the further course of the reaction. Since in the average two molecules of FITC were bound to CA, we must assume more than one Ab molecule attached to the protein in the primary Ag–Ab complex in order to account for the maximum quenching. Since there was no further fluorescence quenching in the course of the growth of the Ag–Ab complexes, and since practically all Ag molecules were bound to Ab in the first few seconds of the reaction, the growth of the Ag–Ab complex may be visualized as linking together the initially formed Ag–Ab complexes.

The light scattering, as it was measured in these experiments, thus measured the growth of the initially formed Ag–Ab complexes. The rate of this growth must depend on the available combining sites of Ag and Ab, and probably on the structure and configuration of the primary Ag–Ab complex. The rate of the reaction as measured by light scattering was significantly different for the various Ag–Ab systems used in this investigation. Similar sets of curves as shown in Fig. 1 for the FCA–AFCA systems were also obtained for the FCA–ACA, CA–AFCA and CA–ACA systems. The maximum reaction rates attained at various Ag concentrations in the above systems are shown in Fig. 3.

The rate of the formation of the primary Ag–Ab complexes, as measured by SAS precipitation of the bound FCA or ICA, was practically identical in the ICA–ACA, FCA–ACA, ICA–AFCA and FCA–AFCA systems at the optimum Ag/Ab precipitation ratios. This was also true in the Ab excess zone, though slightly more time (10–20 sec) was necessary to achieve maximum SAS precipitation.

These findings indicate that the light scatter is a sensitive indicator for measuring differences in reaction rates between different Ag–Ab systems. The primary Ag–Ab complex formation occurred within 10 sec in all the systems studied at the optimum Ag/Ab precipitation ratios; this time interval was inconveniently small to detect differences in the rate of formation of the primary Ag–Ab complex by the techniques used. The light scatter changes, which according to our interpretation measure the rate of growth of the primary Ag/Ab complex, are more convenient to measure and, as the data of Fig. 3 show, give significantly different values for closely related Ag–Ab systems. Since the rate of the reaction

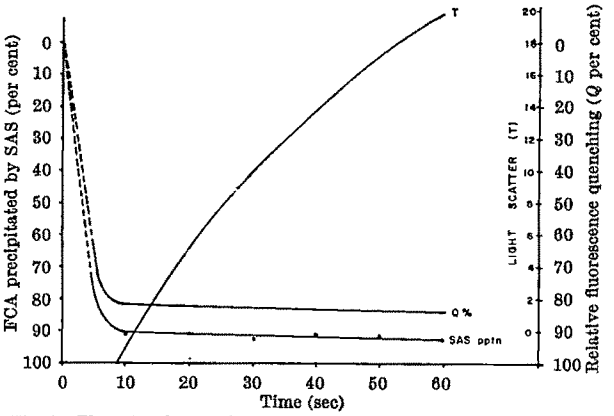

Fig. 2. The rate of formation of soluble Ag–Ab complexes in the FCA–AFCA system at the optimum Ag/Ab precipitation ratio. Protocol: 10 ml. Ab-W (1·46 mg Ab) – 1·0 ml. Ag (0·20 mg): 1·0 ml. aliquots precipitated with 1·0 ml. SAS in 10 sec intervals. 1·2 ml. aliquots used for fluorescence quenching or light scatter measurement. $Q\% = \frac{F_f - F_b}{F_f} \times 100$ where F_f is the fluorescence of free FCA and F_b is the fluorescence of the Ag–Ab mixture. The fluorescence quenching and light scatter curves are redrawn from actual recorder tracings

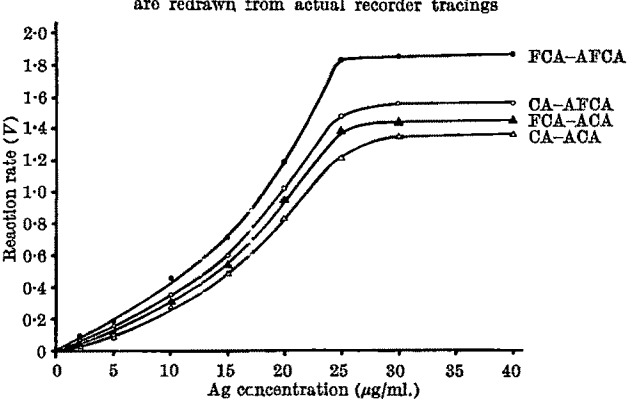

Fig. 3. The effect of Ag concentration on the rate of the Ag–Ab reaction. $V = \frac{dT}{dt}$ sec^{-1}; where T is the light scatter and t is the time in seconds. V was determined graphically from the tangent drawn to the steepest part of the light scatter curves such as shown in Fig. 1

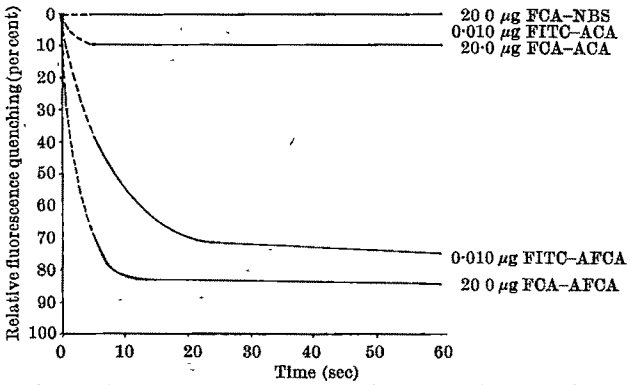

Fig. 4. Fluorescence quenching in the FCA–AFCA, FCA–ACA, FITC–AFCA and FITC–ACA systems. Protocol. 1·0 ml. Ab-W (0·146 mg) + 0·1 ml. Ag, mixed in 3–5 sec, fluorescence quenching recorded. The curves are reproduced from actual recorder tracings

depends on the Ag binding sites available on the Ab molecule, the light scatter changes during an immunoreaction are indicative of the combining properties of the Ag–Ab system.

According to this interpretation the higher reaction rate in the FCA–AFCA than in the FCA–ACA system could be explained by the existence of a combining site for the FITC label in the AFCA molecule. The existence of such a combining site was demonstrated by the observed strong quenching of the fluorescence of FITC or FCA in the presence of AFCA but not in the presence of ACA, as shown in Fig. 4.

In conclusion, the data presented here demonstrate the usefulness of the method of combining light scattering, fluorescence quenching and SAS precipitation for studying the rate of formation of Ag–Ab complexes. It also shows that the measurement of light scatter change, which depends on the rate of growth of the initially formed Ag–Ab complex, is a convenient way to determine differences in the relative combining properties of closely related Ag–Ab systems. For this reason light scatter measurements should be eminently suitable for studying structural differences in proteins or other soluble antigens by their relative combining properties with a standard antibody.

BLOOD SAMPLES FROM THE PITUITARY STALK OF THE RAT: METHOD OF COLLECTION AND FACTORS DETERMINING VOLUME

By PROF. W. CURTIS WORTHINGTON, JUN.*
Department of Human Anatomy, University of Oxford

THE neurohumoral hypothesis of the control of the anterior lobe of the pituitary gland involves the concept of specific releasing factors which are secreted by nerve endings in the median eminence and carried by way of portal vessels into the anterior lobe[1]. There is an overwhelming amount of indirect evidence to support this hypothesis, but with the exception of the work of Porter and co-workers[2,4] there is no direct evidence that there are substances in the portal blood which do not occur in equal or higher concentration in blood in other regions. Direct evidence that such factors exist in the portal blood is urgently needed.

The principal reason for this gap in the mass of evidence which supports the neurohumoral theory is the technical difficulty of obtaining portal blood for assay. The purposes of this communication are to describe a surgical technique which makes possible the collection of samples of pituitary stalk blood which are large enough to be assayed, to discuss those factors which determine the success or failure of attempts to obtain portal blood samples, and to describe briefly some vascular phenomena in the pituitary stalk of the rat.

A Technique for obtaining Pituitary Stalk Blood Samples. With the exception of eleven Lister rats used for electrical stimulation, female albino rats of the Wistar strain were used in all experiments. Anaesthesia is induced with 1,000 mg/kg of urethane in 10 per cent solution, administered intraperitoneally, and supplemented with 1/8 to 1/4 that amount if spontaneous movements of the lower jaw or vibrissae persist. Only as much urethane is used as is required for adequate anaesthesia. The animal is immobilized on a standard rat operating board, and the skin and subcutaneous tissues infiltrated with 2 per cent procaine in the midline from the inter-ramal vibrissae to the sternal notch. The skin and subcutaneous tissues are incised in the midline and these tissues, together with the salivary glands, are separated in the midline and removed from the muscles overlying the trachea. Procaine is introduced beneath the pretracheal muscles (passing the needle anteriorly into the region of the larynx), these muscles are separated in the midline along their entire length and a silk suture is passed under the trachea. A small nick is made in the trachea and a polythene tube placed in position and tied.

The midline incision is carried through the lower lip with scissors and haemostasis is secured by the judicious use of a small eye cautery. The floor of the mouth is infiltrated with 2 per cent procaine deeply along the mandibular margin, and a tight suture is placed around each mandibular ramus. The latter procedure secures a degree of haemostasis when the mandible is divided. Long silk sutures are placed in the two sides of the divided lip and used for lateral retraction of the two sides of the jaw. Before dividing the jaw the tongue is infiltrated down to the base with 2 per cent procaine and a suture placed through the tip of the tongue for ease in subsequent manipulation.

The lower jaw is divided in the midline with heavy sharp scissors (not rongures) and the musculature of the floor of the mouth and oral mucosa are divided along the left side of the mandible. If possible, an assistant should be at the operator's left to clamp bleeders at the base of the tongue with 'mosquito' forceps and assist in tying them. A similar cut is made on the right side and any additional bleeders clamped and tied. The incisions along

* Present address: Medical College of South Carolina, Charleston.

the medial border of the mandible should be extended posteriorly but, if the cut is made too deeply and too far posteriorly between the tongue and mandible, the lingual artery will be cut and profuse haemorrhage may occur. The muscles of the floor of the mouth should be cut further posteriorly, layer by layer, the fauces cut, and the tongue retracted. When the soft palate is entirely exposed and the epiglottis is clearly visible adequate exposure has been obtained. Before retracting the tongue permanently, it is wrapped with oxidized cellulose to secure complete haemostasis and, in addition, small squares of oxidized cellulose are placed on the cut edges of muscle and bone where the mandible and the floor of the mouth have been cut.

The soft palate is infiltrated with procaine and incised in the midline with an eye cautery used as a knife. After enough of the soft palate is removed to expose the posterior pharyngeal wall clearly, the mucosa of the posterior pharyngeal wall is scraped away with a small pledget of oxidized cellulose. This is better than cotton wool or bare metal because it reduces bleeding from the mucosa. If bleeding persists, the entire cavity should be lined for five or ten minutes with oxidized cellulose. The rest of the procedure is carried out under a Zeiss binocular dissecting microscope.

Since minutely detailed instructions for the removal of bone cannot substitute for experience, the following general description of the procedure is supplied. A hole is made in the outer table of bone and partially through the spongy bone of the diploë about 1 mm behind the transverse sinus of the basisphenoid bone. This is filled with neurosurgical bone wax and the drill gradually worked forward toward the transverse sinus while the defect is packed with bone wax at frequent intervals. The drill is actually moved gradually through the transverse sinus, pushing bone wax and ground fragments of bone ahead of the drill to pack it. Great care should be used in this stage of the procedure to avoid sudden massive haemorrhage. If such a haemorrhage occurs, a fairly large pledget of cotton wool carrying a mass of bone wax should be at hand for immediate packing into the wound. This massive packing sometimes stops the bleeding and allows time for more definitive packing of the defect in the transverse sinus.

The inner table should be exposed fully as a smooth glistening plate and ground with a small burr to a uniform thinness which 'yields' when touched with the tip of a forceps. This remaining portion of inner table is removed with a fine chisel. A piece of oxidized cellulose is placed on the exposed dura and on the soft tissues lining the incision for a few minutes before proceeding in order to secure complete haemostasis. Occasionally, troublesome dural arterial or large venous bleeders occur. These must be stopped before the dura is removed. If oxidized cellulose fails to stop them, very small pieces of a mixture of finely ground silver nitrate crystals in bone wax may be applied. These applications should be limited to as small an area as possible. Some degree of fixation of the outer surface of the dura can take place without doing damage to the pituitary stalk, but an excess will fix not only the dura but also the arachnoid and the stalk beneath.

When haemostasis has been secured, the dura mater is incised in a V-shaped incision (the point of the 'V' lying just anterior to the median eminence) and the flap is retracted posteriorly with a No. 5 jeweller's forceps. The arachnoid usually must be incised separately and is retracted in a similar manner. 0·5 ml. heparin (1,000 I.U. ml.) is given by femoral vein after a final check of haemostasis, and the pituitary stalk is cut through with irredectomy scissors at the point of junction with the gland. Initially a small amount of cerebrospinal fluid appears. This is aspirated and discarded.

The blood sample is collected by aspiration into a heparinized length of polythene tubing holding about 0·1 ml. When it is full, the blood is emptied into a heparinized collection tube in an ice bath, by means of a syringe attached to the suction line by a three-way stopcock.

From the incision in the stalk a mixture of blood from three sources is obtained. These are: (*A*) the proximal cut ends of portal vessels (portal blood), (*B*) the distal cut ends of portal vessels (portal back-flow), and (*C*) arterial terminations (arterial blood). There is a marked difference in colour between arterial and portal blood on the one hand and portal back-flow on the other. Portal back-flow is dark blue venous blood and appears to flow freely backward from the dural sinuses through the sinusoids of the pars distalis, and out of the cut ends of portal trunks. Both portal blood and arterial blood are bright red, and, although there is a suggestion of a colour difference, it is slight. Careful preliminary estimation of the apparent amounts of blood from the various sources suggests that portal blood from the median eminence and stalk make up at least 3/4 of any sample, and perhaps more. Any preparation in which a vessel from the dura mater or elsewhere is contributing more than a negligible trickle to the collection is discarded.

General and Surgical Factors affecting Volumes of Blood from the Pituitary Stalk: A. Condition of Animal. In so far as it may be consistent with the design of the experiment, animals in prime condition without prior treatment or manipulation should be used. In this series rats which appeared to be under weight for their group, to have poor coat condition, or the slightest sign of respiratory infection, failed to bleed satisfactorily from the stalk. Those animals which fail to give satisfactory results, even when external signs are absent, usually show some visceral lesions at autopsy.

B. Anaesthesia. Although a wide range of anaesthetic agents has not been used, the choice of anaesthetic agent appears to be important. Sodium pentobarbital anaesthesia is useless since it is known to reduce hypophysial portal blood flow in mice[5], and flow from the cut ends of the pituitary stalk have been negligible when it has been used in the rat. Ether as a supplement to urethane anaesthesia reduces blood flow from the cut ends of the stalk, but urethane anaesthesia alone seems satisfactory. The dose of 1,000 mg/kg gives satisfactory anaesthesia and is usually associated with a preparation from which adequate samples may be collected. In hypophysectomized animals a reduced dose may be necessary. It should be emphasized that very deep levels of anaesthesia make it impossible to collect useful volumes of blood from the stalk. Local procaine anaesthesia during the surgical procedure eliminates reflex responses when the pharynx and trachea are being manipulated and appears to reduce the incidence of shock, circulatory depression and low volumes of stalk sample.

C. Haemorrhage. It has been demonstrated that single large haemorrhages or numerous small haemorrhages reduce portal blood flow in the mouse[5]. This finding is confirmed for the rat. Any animal in which a haemorrhage in the order of 0·25 to 0·5 ml. has occurred is likely to give poor results and if the estimated blood loss during the procedure is as much as 1·0 ml. the preparation should be abandoned.

D. Mechanical Factors. The meninges should be cut through well in front of the median eminence. If the dura is removed too far posteriorly a bulging stalk may exert pressure against the edge of the dura, constricting the portal vessels and reducing flow. Furthermore, attempts to place small cotton wool pledgets between bone and the distal stump of the stalk reduced flow from both the proximal and distal stumps. Any pressure between the bone and pituitary or brain appears to affect the vasculature of the median eminence and stalk sufficiently to cause reduction in flow.

Results of Experimental Procedures on Volumes of Blood from the Pituitary Stalk. A. Hypophysectomy. Pituitary stalk blood samples were obtained from previously hypophysectomized animals. This is important because in such animals the effects of anterior lobe hormones do not have to be considered in assays of stalk blood for

releasing factors, and the necessity for biochemical fractionation is thereby eliminated. Further, it has been found that hypophysectomy increases the amount of luteinizing hormone releasing factor (LRF) in the median eminence of the rat[6] and that in rats hypophysectomized for 45 days LRF is detectable in peripheral blood[7]. Assays of LRF in stalk blood from hypophysectomized animals would not only confirm the presence of LRF in blood in high quantities, but also at an earlier period following the operation. The possible effects of hypophysectomy on other hypothalamic releasing factors is an important area for future investigation and the theoretically higher concentration of such factors in portal blood should make blood from this source superior to peripheral samples.

Hypophysectomized animals present much greater difficulties in obtaining samples of satisfactory volume than intact animals. Even in animals maintained on glucose, saline and a meat diet, the general condition is poor and blood pressure appears much reduced. A moderate to severe intravascular agglutination ('sludging') is present. The blood flow from the stalk is usually so low that 0·5 ml. in 2 h is considered a good yield, and 1·0 ml. an excellent one. During collection, an intravenous infusion of 1:100,000 adrenaline, B.P., at a rate of 0·085 ml./min may increase the flow.

Hypophysectomy also increases the technical surgical problems. The hypophysectomy opening must be avoided when the bone is being removed and the remaining stalk is adherent to the meninges at its cut end, making it difficult to expose as much of the stalk as is possible in the normal animal.

The vessels of the stalk appear to be functional in as short a time as two weeks after removal of the gland. The superior hypophysial arteries have greater diameters than in the normal animal, the capillaries are somewhat engorged and the number of portal vessels appears to be reduced. Occasional abnormally oriented or tortuous portal vessels are encountered. However, despite the intravascular agglutination of the red cells, no thrombosis of capillaries or portal vessels was seen and the blood flow in the portal vessels is in the normal direction (that is, from the median eminence toward the lower stalk). A new secondary capillary network develops in the connective tissues of the sella turcica to replace the anterior lobe sinusoids.

B. Electrical Stimulation. Stimulation of the hypothalamus by electrodes implanted 1 mm. above the floor of the skull and 4·5–5·5 mm anterior to the intra-aural line increased the rate of flow from the stalk. Eleven animals with implanted electrodes were subjected to the procedure described above and stalk blood was collected before and during stimulation at 0·5–1·0 V (25–50 μamp) by a fifty cycle sine wave alternating current. The current was alternatively 'off' and 'on' every 15 sec during the period of stimulation, and the volume of the sample over the total of each time period was determined. The mean value before stimulation of 1·44 ml./h increased with stimulation to 2·28 ml/h. Student's *t*-test shows this difference to be significant ($P < 0.01$).

Assay of Stalk Samples. An assay of pituitary stalk blood samples from proestrus animals for luteinizing hormone activity by the ovarian ascorbic acid depletion method[8,9] shows that 'stalk' blood samples deplete ovarian ascorbic levels significantly and that peripheral blood samples from the same animals do not. This effect is attributed to a mixture of luteinizing hormone and luteinizing hormone releasing factor in the stalk sample. Preliminary studies of blood samples from hypophysectomized animals suggest that they are equally effective. In the latter case the effect must be due entirely to luteinizing hormone releasing factor.

That some back-flow contamination with anterior pituitary hormones is occurring was indicated by determinations of thyroid stimulating hormone (TSH). When 'stalk' blood samples were assayed for this hormone directly by *in vitro* guinea-pig thyroid assay[10], they showed about ten times the concentration of TSH in peripheral blood from the same animal and 5–10 times the level found in normal unoperated animals kept under the same conditions.

In summary, a surgical procedure for obtaining samples of pituitary stalk blood from the rat is described together with some operative, physiological and experimental factors contributing to success or failure in this effort. The importance of obtaining such samples is discussed, and some preliminary results of assays of stalk blood are briefly described.

I thank Prof. G. W. Harris for his encouragement and advice and Dr. Ricardo Nallar for suggestions and assistance.

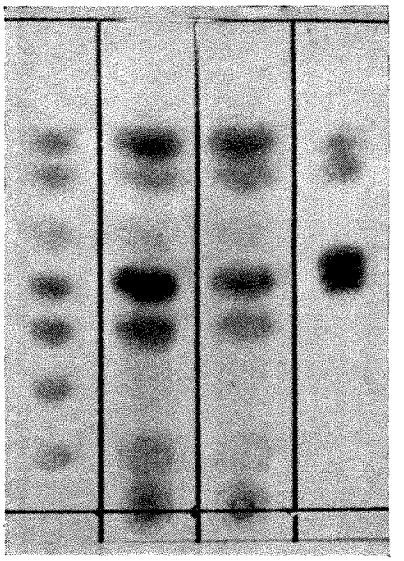
DEFLUORINATION AND HYDROXYLATION OF 4′-FLUORO-4-DIMETHYLAMINOAZOBENZENE BY RAT LIVER *IN VIVO* AND ITS POSSIBLE RELEVANCE TO MECHANISMS OF CHEMICAL CARCINOGENESIS

By J. W. WESTROP and J. C. TOPHAM
Cancer Research Unit, University of Sheffield, Western Bank

THE elucidation of the biological action of any chemical carcinogen requires, in the first instance, a determination of the position(s) in the molecule which, presumably as a result of an interaction with certain tissue elements, is responsible for its activity. An elegant approach towards a solution of this problem was suggested by Miller, Miller and Finger[1]. It involved the use of fluorine-substitution as an indicator of the biologically active or inactive positions in a molecule. The small size of the fluorine atom made it unlikely that the substitution would alter the activity for purely steric reasons. Furthermore, from the fact that the fluorine-carbon bond is among the strongest known, except where the carbon atom is electron-deficient, it was reasoned that any metabolic involvement at a fluorine-substituted position would be highly improbable. These considerations led to the premise that, if a fluorinated molecule was active, the position substituted by the fluorine atom was probably not directly involved in



the biological activity in question. Conversely, if a fluorinated molecule was inactive, then the position blocked by the fluorine atom might participate in the biological activity of the non-fluorinated molecule.

The Millers and their associates have made systematic investigations of the carcinogenic activity of the fluorine-substituted rat hepatocarcinogen, 4-dimethylaminoazobenzene[1,2], and of two other types of carcinogen, 2-acetylaminofluorene[3] and 10-methyl-1:2-benzanthracene[4]. The activity of fluorine-substituted derivatives of the carcinogenic heterocyclic compound, tri*cyclo*quinazoline[5], has been investigated by others. From these extensive investigations, conclusions were drawn regarding the positions in these molecules which most probably were concerned in their carcinogenic activity. These conclusions have achieved a wide measure of acceptance since, hitherto, the belief in the metabolic inertness of a fluorine-substituted position in these compounds has not been questioned by evidence to the contrary. Such evidence, albeit relating to only one of the carcinogens used in the work above, forms the subject of this report. It arose as an incidental finding during an investigation into the nature of the dye metabolites in the liver of rats dosed with 4-dimethylamino-azobenzene.

4-dimethylaminoazobenzene (DMAB) was administered intragastrically in a dose of 20 mg in 1 ml. olive oil/100 g body-weight to adult Wistar rats (usually groups of 4 to 6) which were killed by decapitation 5 h later. The pooled livers were extracted repeatedly by maceration with ether in a blender until no further free dye could be removed. The total ether extract was evaporated to dryness, the residue dissolved in benzene, and the dyes extracted into dilute hydrochloric acid. The dyes were thereby freed from lipids which otherwise interfered with their subsequent chromatographic separation. After adjustment of the acid extract to *p*H 3 with potassium hydroxide and potassium dihydro-*ortho*phosphate, the total basic and amphoteric (hydroxylated) dyes were re-extracted into benzene. This solution was concentrated so that the metabolites from 1 g liver were contained in a volume of 10 μl. This quantity was spotted on silica gel *G* plates and submitted to thin-layer chromatography using the technique described elsewhere[6].

The dye administered, DMAB, together with its known metabolites[7], 4-methylaminoazobenzene (MAB), 4-aminoazobenzene (AB), 4′-hydroxy-DMAB and 4′-hydroxy-MAB, were readily identified (Fig. 1*B*). Two further metabolites were evident and they were shown to be 4′-hydroxy AB and 4′-hydroxy-N-acetyl AB from their chromatographic identity with authentic specimens. Confirmation of this was afforded since the latter metabolite could be converted into the former by mild acid hydrolysis and both, on reductive cleavage with tin and hydrochloric acid, gave the required *p*-aminophenol and *p*-phenylene diamine which were detected by Böniger's reaction as used by the Millers[8].

Groups of rats were treated similarly with 4′-fluoro-DMAB and the metabolites in the liver were isolated and examined in the same way. It was expected that 4′-hydroxylation would be blocked in this compound with the possibility that hydroxylation might occur elsewhere in the molecule. Surprisingly, the chromatographic pattern of the metabolites (Fig. 1*C*) was the same, qualitatively, as that already described for the DMAB-treated rats. The spots which corresponded to the four hydroxylated derivatives obtained from the DMAB-dosed rat liver were removed, in replicate, from the chromatograms. Each of them, on reductive cleavage, yielded *p*-aminophenol (Böniger's reaction), which established that the liver of rats treated with 4′-fluoro-DMAB contained the same 4′-hydroxylated metabolites as those treated with the unsubstituted dye. The possibility that hydroxylation had occurred at a position different from the 4′-position was unlikely because the 2′-, 2- and 3′-hydroxy derivatives of DMAB were easily separable and

Fig. 1. Thin-layer chromatogram: solvent, 10 per cent methanol in benzene, 10 cm run. Dyes listed in order of decreasing R_F. Stable colours of spots after exposure to hydrochloric acid given in parenthesis. *A*, Mixture of DMAB (rose), MAB (orange), AB (orange), 4′-hydroxy-DMAB (purple), 4′-hydroxy-MAB (purple), 4′-hydroxy-AB (purple-red) and 4′-hydroxy-N-acetyl AB (orange); *B*, dye metabolites in liver of DMAB-dosed rats; *C*, dye metabolites in liver of 4′-fluoro-DMAB-dosed rats. The 4′-hydroxy-AB, though readily seen on the original plate, does not show in the photograph; *D*, mixture of 1 μg each of 2′-hydroxy-DMAB (mauve), 2-hydroxy-DMAB (yellow), 3′-hydroxy-DMAB (rose) and 4′-hydroxy-DMAB (purple)

distinguishable from 4′-hydroxy-DMAB in the chromatographic system (10 per cent methanol in benzene) used (Fig. 1*D*).

Although the chromatograms obtained with this system suggested that rats treated with either 4′-fluoro-DMAB or DMAB gave the same non-hydroxylated metabolites, namely DMAB, MAB and AB (compare *B* and *C*, Fig. 1), this was shown not to be the case. Thin-layer chromatography with xylene as developing solvent permitted the separation of 4′-fluoro-DMAB from DMAB (Fig. 2*D*). In this system the hydroxylated dye metabolites remained at, or near, the origin. It may be seen (Fig. 2*B* and *C*) that the three non-hydroxylated dyes in the 4′-fluoro-DMAB-treated rat liver extract had mobilities increased by a relatively constant amount over those of DMAB, MAB and AB, respectively, present in the extract from the DMAB dosed rats. The spot of greatest mobility was evidently the administered dye, 4′-fluoro-DMAB, and the two others were assumed to be the *N*-demethylated metabolites, 4′-fluoro-MAB and 4′-fluoro-AB. Usually, spots corresponding to DMAB, MAB and AB also were seen in chromatograms of 4′-fluoro-DMAB-treated rat liver extract but in barely detectable amounts. It would appear, therefore, that hydroxylation is concomitant with defluorination or that the latter is a distinct reaction followed very rapidly by hydroxylation at the position vacated by the fluorine atom.

The quantitative distribution of the administered dyes and their metabolites in the liver of rats treated with either DMAB or 4′-fluoro-DMAB is shown by a typical experiment (Table 1). The metabolite spots (replicated where necessary) were scraped off the plates and eluted into alcoholic hydrochloric acid. The amount of each metabolite was estimated by spectrophotometric comparison with known quantities of synthetic samples which were similarly chromatographed on, and eluted from, a silica gel *G*-coated plate. Estimates of the total 4′-hydroxylated metabolites also were obtained by a quantitative adaptation of Böniger's reaction for the determination of the *p*-aminophenol obtained on reductive cleavage of total dye extracts. The *p*-aminophenol formed was compared with that obtained when known amounts of 4′-hydroxy-DMAB were taken through the same pro-

Table 1. FREE DYES IN LIVERS OF RATS DOSED WITH DMAB AND 4′-FLUORO-DMAB

Dye	μg Free dye/g liver: DMAB-dosed rats	4-Fluoro-DMAB-dosed rats
DMAB	1·5	—*
MAB	0·4	—*
AB	2·2	—*
4′-Fluoro-DMAB	—	3·4
4′-Fluoro-MAB	—	1·2†
4′-Fluoro-AB	—	0·6‡
Total non-hydroxy dyes	4·1	5·2
4′-Hydroxy-DMAB	4·2	0·8
4′-Hydroxy-MAB	1·9	0·3
4′-Hydroxy-AB	2·8	1·7
4′-Hydroxy-N-acetyl AB	3·1	0·9
Total hydroxy dyes	12·0	3·7
Estimated total hydroxy dyes§	11·5	3·9

* Trace detectable on chromatograms, but below level of estimation.
† Assuming recoveries and E_{max} values similar to those for MAB.
‡ Assuming recoveries and E_{max} values similar to those for AB.
§ Values calculated as 4′-hydroxy-DMAB from determination of yield of *p*-aminophenol obtained on reductive cleavage of the total dyes in the liver extracts.

cedure. Good agreement between the two methods of estimation of the 4′-hydroxylated metabolites was obtained. The total amount of non-hydroxylated dye in the liver was about the same when the rats received either 4′-fluoro-DMAB or DMAB. Rats treated with the fluorinated dye, however, showed a liver content of the total hydroxylated dye metabolites only about one-third of that of those given DMAB itself.

It might be objected that the demonstration of 4′-hydroxylated metabolites in the liver of 4′-fluoro-DMAB-dosed rats might have arisen through the adventitious presence of DMAB in the 4′-fluoro-DMAB used. This was discounted for two reasons. (1) Chromatography of 1 μg of 4′-fluoro-DMAB gave one spot only. A mixture of 1 μg of the fluoro-dye and 0·025 μg of DMAB was easily resolvable into two spots. Therefore, the level of contamination of the former dye by the latter was certainly below 2·5 per cent. (2) Even on the assumption of a 5 per cent level of contamination, a rat dosed with 20 mg of 4′-fluoro-DMAB would receive only 1 mg of DMAB. Dye metabolites, hydroxylated or otherwise, could not be detected by the standard procedure in the livers of rats given this amount of DMAB.

Clearly, the present report by itself cannot be construed to invalidate the conclusions regarding the molecular positions which have significance for the activity of those chemical carcinogens which have been investigated by the method of fluorine substitution. Nevertheless, it does suggest the possibility of metabolism at fluorine-substituted positions in other molecules in which, on theoretical grounds, it would not be expected. It might be considered that regard to this point should be paid to the organic fluoro-compounds which are being introduced increasingly into commerce[9].

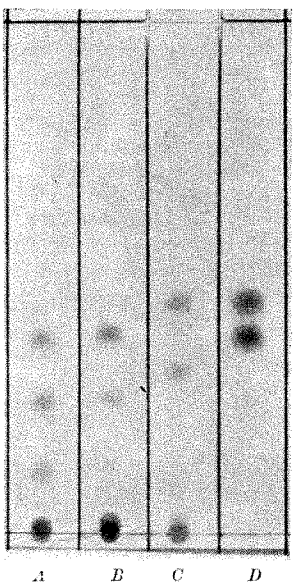

Fig. 2. Thin layer chromatogram: solvent, xylene, 15 cm run. Dyes listed in order of decreasing R_F. Stable colours of spots after exposure to hydrochloric acid given in parenthesis. *A*, Mixture of DMAB (rose), MAB (orange), AB (orange) and their OH-derivatives, which latter remained at or near the origin (purple); *B*, dye metabolites in liver of DMAB-dosed rats; *C*, dye metabolites in liver of 4′-fluoro-DMAB-dosed rats; *D*, mixture of 1 μg each of 4′-fluoro-DMAB (rose) and DMAB (rose)

With regard to the defluorohydroxylation of 4′-fluoro-DMAB, it may be significant that the 4′ position of DMAB is a favoured site for the *in vivo* hydroxylation of the carcinogen. Perhaps the removal of a fluorine atom having a presumed blocking role is effected only under these conditions. It will be of some interest to see if the *in vivo* defluorohydroxylation of the carcinogenic 7-fluoro-2-acetylaminofluorene occurs also. The situation here is analogous to that in the case of 4′-fluoro-DMAB since the 7 position in 2 acetyl-aminofluorene is a site of *in vivo* hydroxylation and, with respect to the substituted amino group, an extended para position.

The defluorohydroxylation of 4′-fluoro-DMAB may have significance in carcinogenesis additional to that mentioned heretofore. Preliminary results have indicated that the very weakly carcinogenic 4′-methyl-DMAB does not undergo appreciable 4′-demethylhydroxylation in the rat whereas the carcinogenic 4′-ethyl-DMAB suffers a fairly substantial replacement of the ethyl by a hydroxyl group. Moreover, under the standard conditions of time and dose, the mouse, which is more refractory than the rat to DMAB hepato-carcinogenesis, 4′-hydroxylated the dye much less efficiently. Guinea-pigs, which are not susceptible to DMAB hepato-carcinogenesis, did not hydroxylate the dye to a detectable extent.

The mechanism of the 4′-defluorohydroxylation of 4′-fluoro-DMAB has not been investigated as yet and may be similar to the defluorohydroxylation of 4-fluoro-phenyl-alanine[10] which requires rat or sheep liver enzymes, oxygen, reduced NADP and tetrahydropteridine. On the other hand, it might be speculated that hydroxylation occurs initially at the substituted amino group of DMAB to produce an aryl-hydroxylamine and that this undergoes re-arrangement, possibly enzyme-mediated, to the 4′-hydroxy-derivative ousting, if necessary, a fluorine atom at this site. Arylhydroxyl-amines have been shown to be produced *in vivo* in susceptible species from many carcinogenic aromatic amines and much evidence has accumulated to suggest that they are proximate carcinogens[11]. So far, this reaction has not been firmly implicated in the carcinogenic activity of the aminoazo dyes although *N*-hydroxy, *N*-acetyl-AB has been identified recently[12] in the urine of rats dosed with AB. It is interesting that the isomeric 4′-hydroxy-*N*-acetyl AB was one of the metabolites found in the liver of our DMAB and 4′-fluoro-DMAB-treated rats.

We thank Dr. W. J. P. Neish, of these laboratories, for gifts of some of the aminoazo dyes, Miss J. Oates for technical help and the Yorkshire Council of the British Empire Cancer Campaign for Research for their financial support.

ACCELERATING AND DECELERATING ACTIONS OF ADRENALIN ON EPIDERMAL MITOTIC ACTIVITY

By PROF. W. S. BULLOUGH and E. B. LAURENCE
Birkbeck College, University of London

FROM a series of investigations of the action of adrenalin on mouse epidermis it has been concluded[1-3], first, that this hormone inhibits the entry of cells into mitosis, and second, that it prolongs the duration of mitosis in those few cells which manage to overcome the inhibition. The antimitotic action of adrenalin on epidermis was first reported by Friedenwald and Buschke[4] and has since been confirmed, for example, by Chaudry, Halberg and Bittner[5], Chiakulas, Scheving and Winston[6], and Bogoyavlenskaya and Dobrokhotov[7].

Recently, however, Evensen[8] and Evensen and Heldaas[9], using the epidermis of hairless mice, have come to a directly contrary view that adrenalin increases the mitotic rate and decreases the mitotic duration. Evensen[8] has further concluded that with a high mitotic rate colcemid loses its power to arrest cells in metaphase when in the presence of adrenalin, and if this is true then much earlier work is invalidated. It has thus become necessary to re-examine the whole problem and to obtain further evidence.

In this new investigation the mice used were all adult males of the Kreyberg *WLL* and Strong *CBA* strains, and only slight differences were found between them. They were killed by neck-pulling and small pieces of ear were immediately transferred to a phosphate-buffered saline medium with glucose (for techniques see refs. 10 and 11). After various periods of time the pieces of ear were fixed and sectioned at 7μ, and the epidermal mitoses were counted in unit section lengths.

An investigation was first made of the effect of adrenalin on those mitoses that were already in existence when the ears were separated from the bodies. Each Warburg flask contained five pieces of ear from different mice and the adrenalin was placed in the side arm. After all the flasks had been set up and were in the constant temperature bath, the adrenalin was tipped in. Then, at each interval of 5 min, one flask was opened and the pieces of ear were immediately fixed. The results are given in Table 1. The figures, taken together with the observations on the phases of mitosis, indicate: (1) that the many mitoses present when the adrenalin was added passed quickly to completion—all prophases disappeared in about 10 min and all metaphases in about 20 min; (2) that in the presence of adrenalin, the time taken for the whole process of mitosis was probably less than 1 h, as compared with a normal *in vitro* time of about 2·8 h (see Table 2); (3) that after about 30 min small numbers of new mitoses began to appear.

Table 1. EFFECT OF ADRENALIN ON THE MITOTIC ACTIVITY OF MOUSE EAR EPIDERMIS DURING THE FIRST HOUR *in vitro*

Time (min)	No. of mitoses	Phases of mitoses
0	6·8 ± 0·23	All phases present
5	6·7 ± 0·43	All phases present
10	5·1 ± 0·54	No prophases
15	4·8 ± 0·37	Few metaphases
20	3·0 ± 0·41	All in telophase
25	2·0 ± 0·17	All in telophase
30	1·4 ± 0·09	Few pro- and metaphases
35	1·3 ± 0·29	Few pro- and metaphases
40	0·9 ± 0·15	Few pro- and metaphases
45	0·5 ± 0·19	All phases present
50	0·3 ± 0·11	All phases present
55	0·4 ± 0·37	All phases present
60	0·2 ± 0·08	All phases present

Average numbers of mitoses in unit lengths of 1 cm. ear epidermis sectioned 7μ thick.

N, Five mice. Adrenalin concentration, 0·25 μg/ml.

Note: In control ear epidermis the mitotic count falls only slightly and at 60 min = 5·6 ± 0·42 (N = 5).

Table 2. EFFECT OF ADRENALIN ON THE MITOTIC ACTIVITY OF MOUSE EAR EPIDERMIS DURING THE SECOND TO THE FIFTH HOUR *in vitro*

Culture medium	Metaphases arrested by colcemid in 4 h		All phases of mitosis at hourly intervals (no colcemid)		Duration of mitosis $\Sigma M_2/M_1$
	N_1	M_1	N_2	M_2	(h)
Control	10	7·6 ± 0·18	50	4·7 ± 0·23 5·1 ± 0·27 5·5 ± 0·32 4·8 ± 0·22 0·5 ± 0·18	2·6
With 0·25 μg adrenalin/ml.	15	0·5 ± 0·14	15	0·4 ± 0·11 0·6 ± 0·21 1·4 ± 0·29	5·8

Average numbers of mitoses in unit lengths of 1 cm of ear epidermis sectioned 7μ thick. *N*, Number of mice.

This indication of an increased speed of completion of mitosis is in agreement with Evensen[8] and Evensen and Heldaas[9] and contradicts the conclusion[3] that the addition of adrenalin can prolong mitosis to almost 6 h. However, this conclusion did not refer to already existing mitoses but only to mitoses that commenced between the second and fifth hour after the addition of adrenalin. In Table 2 the behaviour of epidermal cells at this time is shown by the combined results of ten separate experiments. These figures suggest: (1) that adrenalin inhibits mitotic activity by preventing cells from entering mitosis; (2) that with the concentration used, adrenalin causes an increase in mitotic duration from about 2·8 h to about 5·8 h.

However, these suggestions can be challenged if Evensen[8] is correct in concluding that adrenalin so interferes with the action of colcemid that in the adrenalin-treated epidermis few, if any, mitoses are arrested in metaphase. This conclusion suggests the possibilities: (1) that the lower mitotic counts obtained with adrenalin in the absence of colcemid were the combined results of an increased mitotic rate and a reduced mitotic duration; (2) that the lower mitotic counts obtained with adrenalin in the presence of colcemid were due in addition to the neutralization of the colcemid action.

Both these possibilities can be countered if it can be shown that adrenalin has no effect on colcemid action. In the present colcemid experiments (Table 2) it was found that in both the control and the adrenalin-treated epidermis almost all the mitoses were indeed arrested in the metaphase, but a further test of colcemid action was made using wounded epidermis. Such epidermis, both *in vivo* and *in vitro*, shows a high mitotic rate and a short mitotic duration, both of which are relatively unaffected by adrenalin (for an explanation of this phenomenon see refs. 2 and 12). The effects of adding both adrenalin and colcemid to such epidermis *in vitro* are seen in Table 3. This shows that since no significant differences exist between the figures for the control and the adrenalin-treated

Table 3. EFFECT OF ADRENALIN AND COLCEMID ON THE MITOTIC ACTIVITY IN WOUNDED MOUSE EAR EPIDERMIS *in vitro*

Culture medium	Metaphases arrested by colcemid in 4 h		All phases of mitosis at hourly intervals (no colcemid)		Duration of mitosis $\Sigma M_2/M_1$
	N_1	M_1	N_2	M_2	(h)
Control	56	11·4 ± 0·29	34 34 22 28	6·2 ± 0·27 5·2 ± 0·29 4·1 ± 0·27 4·7 ± 0·22	1·8
With 0·25 μg adrenalin/ml.	40	10·5 ± 0·47	31 32 32 36	5·6 ± 0·41 5·3 ± 0·27 4·0 ± 0·21 4·5 ± 0·24	1·8

Average numbers of mitoses in unit lengths of 1 mm of sections cut 7μ thick of epidermis immediately adjacent to a 2-day-old wound edge. *N*, Numbers of wounds.

epidermis, and since in both the colcemid-treated groups all the mitoses were arrested in metaphase, the action of colcemid was not affected by the adrenalin. This is an important conclusion since most previous investigations of adrenalin action on mitosis have involved the use of either colcemid or colchicine.

The most important conclusion emerging from these results is that adrenalin has a double action on the mitotic process. It accelerates the rate of completion of already existing mitoses and it decelerates both the entry of new cells into mitosis and the rate of completion of such mitoses. Adrenalin is known to accelerate many physiological processes and the stimulus to existing mitoses may perhaps be part of this general action. The blockage of mitosis in antephase (or G_2) has been ascribed to the joint action of adrenalin with a tissue-specific chalone, which forms an essential part of the mitotic homeostatic mechanism of the tissue[2]. It has been further suggested that the chalone–adrenalin inhibitor operates on the mitosis genes[12], in the manner of a bacterial effector substance, and that mitotic duration may be inversely related to the concentration of essential metabolites formed under gene instruction in antephase[13]. If this is true then the reduced antephase syntheses caused by an excess of chalone-adrenalin inhibitor could lead to the slower completion of mitosis, or even to complete inhibition. These are matters for further investigation.

RELATIVE GROWTH OF TROPHOBLAST AND TUMOUR CELLS CO-IMPLANTED INTO ISOGENIC MOUSE TESTES AND THE INHIBITORY ACTION OF 'METHOTREXATE'

By DR. J. B. SOLOMON*

Chester Beatty Research Institute, Institute of Cancer Research, Fulham Road, London

THE first person to direct attention to the similarities between trophoblast and tumour cells was Beard[1] in 1902; this author[2] later described cancer cells as "irresponsible trophoblasts". Since this time, the many properties which trophoblast cells have in common with tumour cells have been frequently reiterated[3–5]. Some of these properties are listed in Table 1.

Table 1. COMPARISON OF SOME GENERAL PROPERTIES OF TROPHOBLAST AND TUMOUR CELLS WHEN BOTH ARE RAPIDLY PROLIFERATING

Trophoblast	Tumour
Highly invasive	Invasive
Can metastasize	Many can metastasize
Can resist homograft rejection	Can resist homograft rejection
Cannot be serially transplanted	Can be serially transplanted
Uncontrolled trophoblastic growth →	Chorionepithelioma

The trophoblast is one of the most primitive of embryonic cells, being an extra-embryonic derivative of the blastocyst. Trophoblast cells, during their invasive period, are the most highly invasive and destructive cells known; they are more active in both these respects than any known malignant cells. Conversely, tumour tissue has been described as an analogue of the implanting mouse embryo[6]. The greatest difference between the two cell types is in the limited period of invasive growth and overall life span of the trophoblast due to termination of pregnancy; in contrast, many tumours possess an autonomy which enables them to be serially transplanted. When trophoblastic growth becomes uncontrolled the neoplastic trophoblast (chorionepithelioma) is still histologically and endocrinologically identical with normal trophoblast except in its uncontrolled behaviour.

It has been suggested[7] that benign tumours exhibit all the characteristics of tumour growth except that of malignancy, so that comparison of benign and malignant tumours should yield information on the malignant properties of the cancer cell. Comparison of the trophoblast with malignant tumour cells will take us a stage further than this in enabling a direct comparison to be made of the 'malignant' properties of invasiveness and destruction of normal embryonic cells with those of malignant cells.

* Present address: Department of Microbiology, University of Adelaide, South Australia.

Few experiments on the co-implantation of trophoblast and tumour cells have been reported. Runner[8] co-implanted mouse blastocyts with mammary carcinoma into the anterior chamber of the mouse eye and observed that both implanted tissues grew for 5–7 days, but unfortunately no further observations were made. The trophoblast grows more rapidly in organs such as the spleen[9] and testis[10] than in the uterus; the testis is the most favourable host organ for growth that has yet been tried[10]. In the present article, the behaviour of trophoblast and tumour cells rapidly growing together in isogenic mouse testis is described. The effect of administering 'Methotrexate' to mice bearing testicular single implants or co-implants of trophoblast and tumour has also been studied. 'Methotrexate' was chosen because it is known to inhibit growth of sarcoma 180 in mice[11], and this compound has some beneficial effects in cases of human chorioncarcinoma.

Ectoplacental cones were obtained from *CBA* mice at 7·5 days of gestation. Deciduomata were taken from the uterus, sliced both sides of the centre to reveal the ectoplacental cone, which was then removed with a very sharp needle. Ectoplacental cones were kept in sterile normal saline for 1–2 h before implantation. Crocker tumour (sarcoma 180) was passaged in *CBA* mice for 6 months by subcutaneous implantation. Tumour tissue was obtained by repeatedly cutting a portion of the external area of the subcutaneous implant until pieces of tumour were just small enough to be drawn into a glass syringe. The bore of this syringe was just large enough to take an ectoplacental cone; in this way fragments of tumour of similar size to the ectoplacental cones were obtained.

The right testis of adult *CBA* males, anaesthetized with ether, was withdrawn after incision of the skin and body wall. The tunicae of the testis were pierced with a sharp needle and the glass syringe inserted. The tumour and ectoplacental cone were ejected by blowing through the syringe. The hole in the tunicae was sealed with a drop of collodion and the testis returned to the scrotum. Skin and body wall were clamped with two small metal clips.

Histological examination of the implanted testis was made from 3–10 days after implantation by selecting every fiftieth section of the testis and staining with haematoxylin-eosin. Growth was estimated by the total area occupied in all the serial sections. The results of 75 successful implantations are reported. 'Methotrexate' tablets (Lederle Laboratories) were dissolved in sterile normal saline, the solution filtered and injections made intraperitoneally.

The growth pattern of single implants of trophoblast or tumour into the testis were first studied. Proliferation of trophoblast cells in the absence of tumour cells does not begin until between 3–4 days after implantation; at 5 days, the trophoblast cells are dividing rapidly and invading the testicular tissue. At this time, the trophoblast area is filled with typical giant cells (Fig. 1). Two days later, about one-quarter to one-third of the testis has been eroded away and the giant cells line a sac containing chiefly red cells (Fig. 2). To test whether the 'mass action' transplantation phenomenom applied, two ectoplacental cones were implanted together. There was mutual enhancement of the rate of growth of both trophoblasts, the areas of which were very much greater at 3 days after implantation than those of single implants. Seven days after implantation the two trophoblasts occupied the entire testis (Fig. 3).

Implants of tumour alone appeared to grow somewhat less rapidly than those of trophoblast alone during the first 5 days after implantation. At 7 days, the area of testis invaded by tumour cells was usually considerably less than that occupied by trophoblast derived from a single ectoplacental cone.

Co-implantation of tumours and trophoblast resulted in a very small focus of proliferating cells at 3 days after implantation. This consisted chiefly of trophoblast cells in active mitosis and a few giant cells were also visible. This was a similar stage of growth to that of trophoblast implanted alone after 5 days. Tumour cells were also rapidly dividing, but occupied only about one-twentieth of the area of the trophoblast cells. There was some evidence of phagocytosis of a few of the tumour cells by the invading trophoblast. Seven days after implantation the trophoblast had eroded the same area of testis as that due to a trophoblast implanted alone; however, the area occupied by the tumour was greatly increased above that normally found for a single implant of tumour alone (Fig. 4). Examination of the junction of trophoblast and tumour cells (Fig. 5) showed some degree of phagocytosis of the tumour cells but otherwise both giant and tumour cells appeared normal. Ten days after implantation the

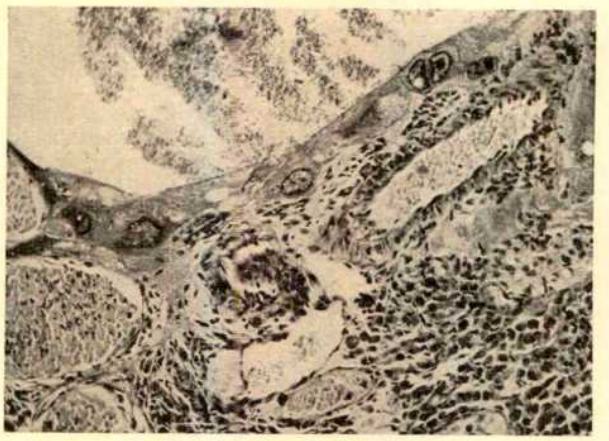

Fig. 5. Neighbouring trophoblast and tumour cells

trophoblast area had diminished considerably and appeared to have been occupied by tumour cells.

In experiments designed to inhibit trophoblast and tumour growth, 'Methotrexate' was administered 2 h after implantation and then daily for the following 3 days. Testes were removed 6 days after implantation. Doses of 'Methotrexate' are expressed as the total dose given during the experiment. Small doses of 'Methotrexate' (0·15 mg) had no effect, but double this dose (0·3 mg) produced some slight inhibition of tumour growth but did not inhibit trophoblastic growth. Larger doses of 'Methotrexate' (1·0 mg) completely inhibited growth of single implants of tumour in 80 per cent of the mice; in the remainder, tumour growth was only just discernible. At this dose level and a higher level (2·0 mg) the trophoblast area was reduced about four-fold (Fig. 6), but was histologically identical with trophoblasts in normal mice. No tumour cells were visible at these higher dose levels in the co-implanted testes.

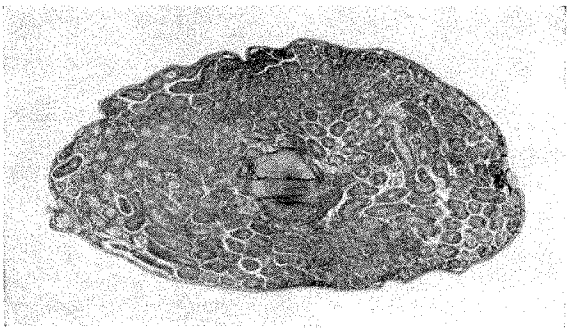

Fig. 6. Effect of 'Methotrexate' (1·0 mg) administered to host mice on the growth of trophoblast and tumour. Trophoblast growth has been severely inhibited and no tumour growth can be seen

The phenomenon of enhanced tumour growth in the presence of rapidly dividing embryonic cells is well documented[12–14]. However, adult cells when transplanted with tumour cells fail to enhance tumour growth. It has been suggested that embryonic cells provide a primary stroma[15] or a more favourable matrix[14] for the initiation of tumour growth. In the present work it has been shown that not only is tumour growth enhanced by the presence of actively dividing trophoblast cells but that initial growth occurs sooner after implantation. In the same way, one trophoblast may enhance the growth of a neighbouring trophoblast. The milieu of a rapidly dividing cell population may induce more rapid proliferation in a neighbouring cell population. How this occurs is not yet known.

The invasiveness of trophoblast in the testis has been fully described[10]. Destruction of testicular tissue occurs after infiltration of trophoblast cells between the seminiferous tubules and takes place by lysis rather than by phagocytosis. Kirby[10] suggests that a cytolytic agent diffuses ahead of the advancing trophoblast as he observed a layer of cell debris and extravasated blood between the trophoplast and the seminiferous tubules. No phagocytosis of unchanged testicular tissue has been observed in either Kirby's or the present work, but a few tumour cells appear to be ingested by the trophoblast cells. Generally, both trophoblast and tumour cells appear to coexist quite normally at the junction of the two-cell types. The essentially normal appearance of host tissue next to the invading trophoblast has also been observed in other host organs such as the spleen[9]. Not all cells cohabit with trophoblast tissue; in the same way some organs such as the liver are not suitable sites for implantation of trophoblast (D. R. S. Kirby, private communication). Tao[16] has shown that, whereas autologous trophoblast–lung cell mixtures are compatible *in vitro*, trophoblast–liver mixtures are mutually incompatible and necrosis of both cell types occurs.

In the present work, observations have generally been made quite soon after implantation during the maximal growth and invasive phase of the trophoblast in order to avoid studying testes in which implant growth has been restrained due to lack of *lebensraum*. As trophoblast is the first cell to begin actively proliferating and invading the testicular tissue it is somewhat surprising, under these circumstances, that nearly all the tumour implant is not engulfed and destroyed. However, as soon as the trophoblast begins to proliferate the milieu of active cell division appears to stimulate earlier division of the tumour cells and, although some are undoubtedly phagocytosed by trophoblast cells, sufficient survive to produce eventually greater tumour growth than normal. The ingestion of tumour cells does not appear to occur frequently, as the tumour seeks to evade the rapidly approaching 'front' of giant cells by invading neighbouring testicular tissue. In this way, both tumour and trophoblast cells make full use of the *lebensraum* of the host organ. This impression is confirmed by the work of Cole and Paul[17], who found that trophoblast cells from mouse blastocysts implanted on to a monolayer of HeLa cells migrated outwards in typical fashion and that the HeLa cells preferred to retreat rather than be engulfed. When ectoplacental cones were implanted into spontaneous mammary carcinomata the trophoblast cells actively invaded and eroded the tumour tissue[19]. It appears that trophoblast always has the strategic advantage of rapid proliferation even in an environment, such as a tumour, when it might be expected to be destroyed during the latent period immediately following implantation, before proliferation of the implant begins.

The present trophoblast–tumour model offers an ideal situation for testing drugs for specific anti-tumour effects. It is an essential of this model that the tumour cell be nearly as rapidly dividing as the trophoblast cells. In the case of the Crocker tumour (originally a spontaneous mammary carcinoma), although it proliferated less rapidly than trophoblast it was nevertheless more susceptible to 'Methotrexate' than the trophoblast. Such a result suggests some specific anti-tumour action as trophoblast was used as a control. This model may pave the way for future chemotherapeutic tests. In this way, it may now be possible to test for specific anti-tumour drug action rather than general growth-inhibitory effects.

I thank Lederle Laboratories for their donation of 'Methotrexate' and Prof. A. Haddow for his active interest in this work. This investigation has been supported by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the Medical Research Council and the British Empire Cancer Campaign for Research, and by the National Cancer Institute, U.S. Public Health Service.

PHYSICS

Sparkover in Long Uniform-field Gaps

THE object of the work described in this communication was to measure the static breakdown voltages of long uniform-field spark gaps in atmospheric air, and to investigate the mechanism of sparkover. The measurements were made using electrodes of the Bruce profile[1], for which sparkover occurred in a uniform electric field at electrode spacings up to 17 cm.

The gap voltage was obtained from a high-stability electrostatic generator, and measured using a resistance divider of approximately 800 MΩ total resistance: to minimize the effect of the temperature variations on the divider ratio, both arms of the divider were constructed from resistors of the same type, mounted in the same oil-filled container. The output voltage from the divider was measured to within ±0·05 per cent using a digital voltmeter.

All measured sparkover voltages have been corrected to 20° C, 1,013·25 mbars and a humidity of 11 g/m³. In the temperature and pressure correction, the curve given by Bruce[1] was used, and in the humidity correction a factor of +0·2 per cent per g/m³ increase in humidity[2,3]. The comparative accuracy of measurements made under different atmospheric conditions is considered to be ±0·17 per cent while the absolute accuracy is better than ±0·25 per cent.

Preliminary experiments carried out with the gap in the open atmosphere of the laboratory produced an unacceptable scatter in sparkover voltage measurements which was presumably due to dust. The measurements reported here were made using the arrangement of Fig. 1, with the gap in filtered atmospheric air within an aluminium enclosure (8-ft. cube): the inside walls of the enclosure were frequently cleaned.

The following experimental procedure was adopted: After the electrodes had been cleaned and adjusted, air was blown through the enclosure at ~200 ft.³/min for about 2 h; at the same time, a voltage of value ~10 per cent below the expected sparkover voltage was applied to the gap to allow the potential divider to attain temperature equilibrium. Sparkover voltages were recorded 1 h after switching off the blower: after each sparkover, the output voltage of the generator fell to about 10 per cent of the sparkover voltage (V_s) of the gap, before automatically resetting to a value ~0·5 per cent below sparkover voltage. By means of a motor-driven potentiometer, the gap voltage was then increased at approximately 0·5 per cent V_s/min until sparkover again occurred. The time interval between succeeding sparkovers was about 2 min.

At each gap setting, about twenty-five sparkovers were required to stabilize the gap, as shown in Fig. 2. Thereafter, a very stable breakdown condition obtained, with no 'low freak' sparkovers, and the sparkover voltage for the gap was taken as the mean of the next twenty to thirty individual breakdown measurements.

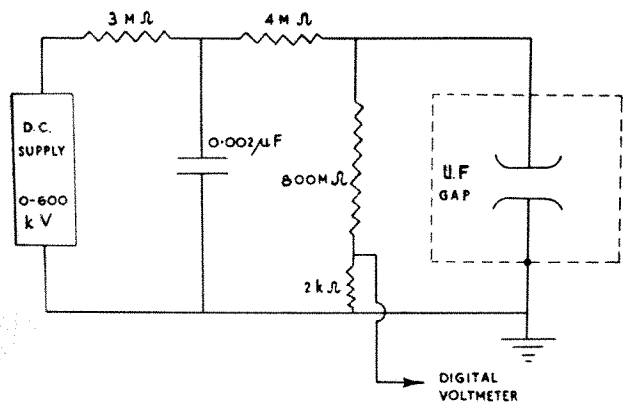

Fig. 1. Circuit diagram

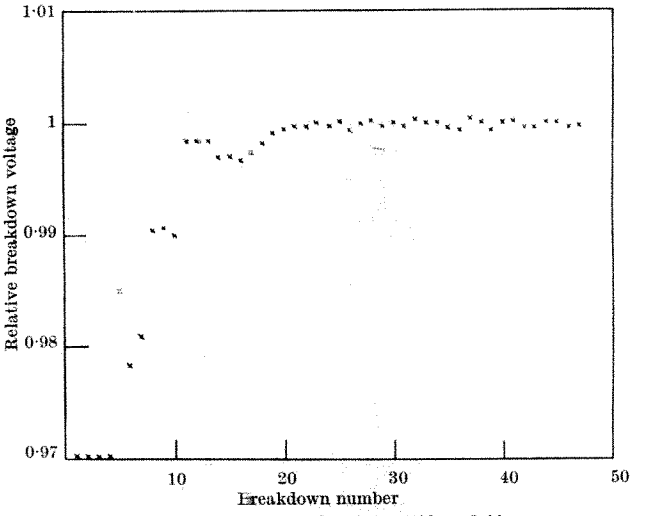

Fig. 2. Sequence diagram for 12-cm uniform field gap

Two series of measurements were made for each gap length, at different times, the mean sparkover voltage in the two cases agreeing within the comparative accuracy of ±0·17 per cent already quoted. The results obtained lie within 0·2 per cent of the values given by:

$$V = 24{\cdot}49S + 6{\cdot}61\sqrt{S}\ \text{kV}$$

where V is the sparkover voltage at 20° C, 1,013·25 mbars and humidity of 11 g/m³, for an electrode spacing of S cm.

In Table 1, the present results are compared with those of Schröder[3], who conducted similar experiments with filtered air and gap lengths of up to 9 cm. The results are in good agreement, but the mean deviations reported by Schröder are considerably greater than in the present work and, in addition, occasional 'low freak' sparkovers were observed during his calibration.

The reduced scatter and absence of 'low freaks' in the present investigation are, we think, due to improved experimental conditions, in particular with regard to dust: the result is significant because of the statement made by Schröder that the scatter in his results was to be expected at the longer gap lengths (> 6 cm), where, he claimed, the Townsend mechanism of breakdown was replaced by a modified 'kanal' mechanism. This claim was supported by oscillograms obtained using a photomultiplier to record the growth of ionization in the discharge gaps at or near the sparking threshold[4].

We have carried out some preliminary work of this kind using a photomultiplier: two forms of oscillogram are obtained, and are shown in Fig. 3. Fig. 3*a* shows succeeding avalanches produced presumably by photoelectric effect at the cathode (Townsend mechanism), while Fig. 3*b* shows an initial avalanche followed by an 'aftercurrent' without evidence of successive Townsend-type secondary avalanches. The 'aftercurrent' was stated by Schröder to

be due to delayed electrons, probably produced by detachment, which, avalanching towards the anode, increase the positive ion concentration and lead to a streamer breakdown: as he obtained oscillograms of type A for $d < 6$ cm and of type B for $d > 6$ cm, he concluded that a transition in mechanism took place in air at a value of pd (pressure × gap length) ≈ 4,500 mm mercury cm. In the present work, however, both types of oscillogram were recorded at all gap lengths investigated (that is, from 3·5 to 12 cm), their relative proportion depending on the surface condition of the cathode, the proportion of type A increasing after polishing and conditioning. It is suggested, therefore, that the large avalanches which gave rise to aftercurrents and apparent streamer breakdown in these experiments may have been initiated, not by single electrons, but by large numbers of electrons released simultaneously from microprojections on the cathode surface and/or dust particles: a similar explanation was proposed by Schröder for the 'low freak' sparkovers observed in his experiments in the non-irradiated condition, and was supported by oscillograms of type B being recorded at all gap lengths when an α-particle source in the cathode was used as irradiating agent.

Further detailed investigations of these concepts, together with knowledge of the elementary ionization, attachment and detachment processes, are necessary before a region for the so-called Townsend-streamer transition can be defined for air. The present experiments are being extended to obtain the necessary data.

The work formed part of a research programme supported by the Central Electricity Research Laboratories and by a special research grant from the Science Research Council.

Very High Precision X-ray Diffraction

VERY high precision has been obtained in the measurement of X-ray diffraction angles, such that if translated into terms of changes in the crystal lattice constant, a precision of 1 part in 10,000,000 can be attained. All indications are that the limit of sensitivity can be extended even further. Fig. 1 shows the application of the method to measurements of the coefficient of thermal expansion of magnesium oxide over a temperature range of 1° C, and gives a clear idea of the sensitivity that is at present being obtained.

The technique involves the use of a specially designed instrument, the 'automatic precision X-ray goniometer'; precise measurements of intensity and angle are made, and special treatment is given to various systematic errors. Tests show that if care is taken to ensure that there is no variation in the atmospheric absorption of the X-rays, due to variations in atmospheric pressure and humidity (preferably by having the instrument in a vacuum enclosure), then the intensity can be kept constant to at least 0·02 per cent for many hours, and so measured to this accuracy—provided certain further precautions are also taken with the X-ray generating and counting equipment.

The angles are measured by counting pulses to a stepping motor connected to a worm and gear as shown in Fig. 2. The crystal is fitted to a holder connected to the gear shaft. The system has the following properties. Originally around the gearwheel, there is an angular error of ±15 sec of arc, but this can be corrected for by means of a cam and the residual error is reduced to ±5 sec. However, tests over ranges of some hundreds of seconds show that the gear is stepped on correctly to better than 0·1 sec, and this represents the basic sensitivity of the method. On the gear, 0° and 360° occupy the same position, so that the diffraction peaks for a reflecting crystal, rotated through 360°, should be in the same position with regard to the gear, with an accuracy that reflects the basic sensitivity, and not the gross overall error. Tests show that this is the case. Thus there is a closed error loop around the gear (that is to say, the sum of the errors is zero), so that if, when an angle is being measured, each part of the gear is used in turn (for example, an angle of 21° would have to be offset $\frac{360}{21} = 17$ times around the gear during measurement), this should also reflect the basic sensitivity of the method in the precision of the result. Tests, consisting of the measurement of angles in this manner, but starting at differing positions around the gear, indicate that this is so. This closed error loop strategy cannot normally be carried out to perfection, and a small overlap at each new position on the gear will usually occur. The effect of this, however, is small, due to the small overall error.

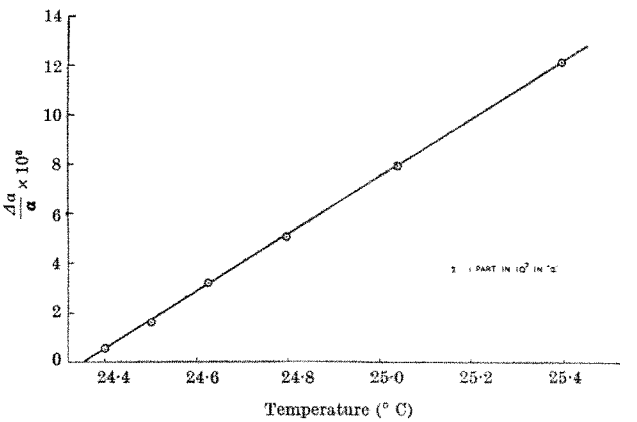

Fig. 1. Thermal expansion of magnesium oxide over a temperature range of 1·0° C

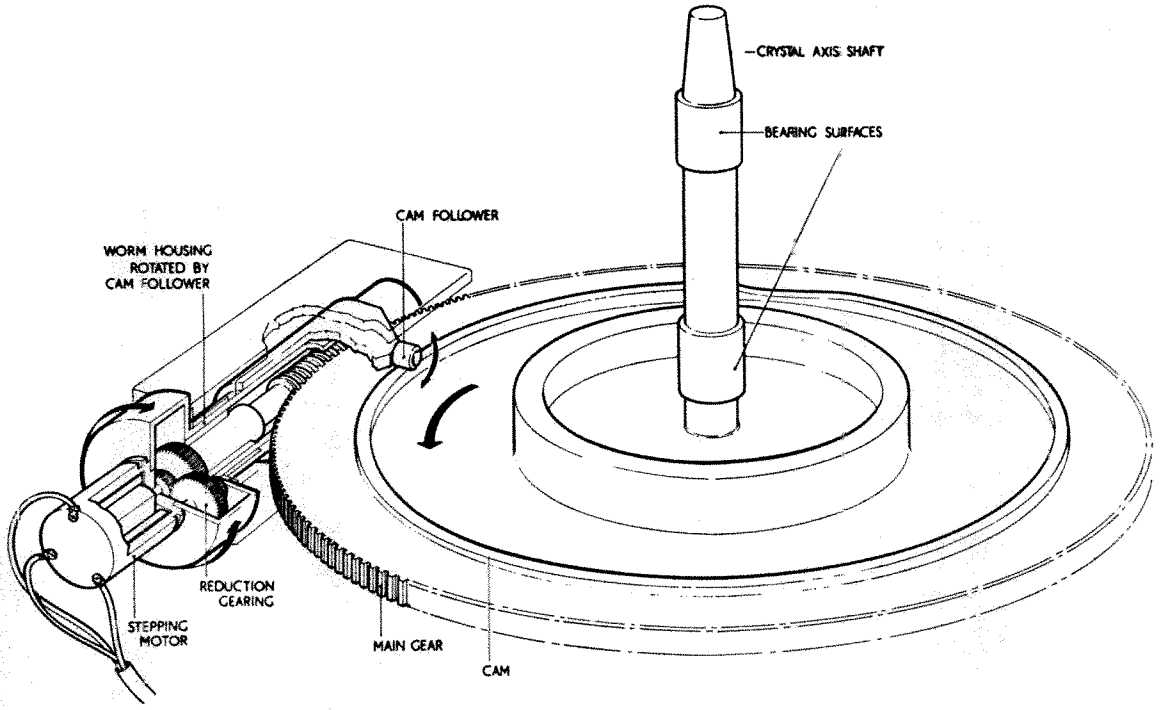

Fig. 2. Method of angle measurement

When applied to problems of diffraction, the method is to measure the angle between two reflecting positions of the crystal, under which conditions, as has been pointed out by Bond[1], errors associated with measurements of the diffracted beam (eccentricity of specimen, absorption, and zero error) do not occur. The method used is basically that of the Bragg spectrometer—the Braggs[2] were clearly aware of the directness of the method.

At the degree of precision dealt with here, there is a further systematic error which requires more stringent treatment than hitherto reported. This is due to the fact that the plane of diffraction may not be sufficiently parallel to the plane of measurement, so that the angle measured is only a projection of the true angle. The plane of diffraction is defined by the directions of the incident beam (that is, the collimator) and the normal to the crystal plane. For a measuring circle in the horizontal plane, errors in the measured angle will occur if either the collimator or crystal has a vertical tilt. A simple procedure has been developed, however, that allows the non-planar conditions, introduced by a collimator tilt of small but unknown magnitude, to be tolerated and which at the same time adjusts the tilt of the crystal to the optimum value. If the crystal is progressively tilted in the vertical plane, the angle between the two reflecting positions of crystal passes through a maximum value, and this maximum value is very close to the correct one, for although non-planar conditions will hold good, the projected angle is very close to the true value. (The reason for this is that in these circumstances the projection function is only changing very slowly.) In practice, the crystal is merely set on the side of a peak, and its tilt is varied until maximum intensity occurs—such conditions result in the maximum angle being obtained. Fairly large tilts of the collimator can be tolerated. For example, at a Bragg angle of 80°, a collimator tilt of 10 min introduces an error of only 0·25 sec in the measured angle, which is equivalent to an error of 1 in 10,000,000 in the crystal lattice constant.

In offsetting the crystal holder around the gear, it is inevitable that small errors in centring and tilting will occur; however, these are allowed for by the method. The instrument is maintained in a thermostatically controlled enclosure and manipulated by remote control; in this way it is protected from outside influences during its operation—an important consideration if the closed error loop method is to be effective. The fact that the procedures can be automatically carried out makes the method particularly convenient. It is arranged that the results are fed into a computer, and a curve is fitted to the profile of the peak, so that small changes of position or shape can be properly described. Graphical constructions of the mid-chord peak can also be used.

Since the peak can be described to 0·02 per cent and 0·1 sec from the point of view of intensity and angle, respectively, it can be used for purposes of calibration, and its subsequent movement measured with, say, changes of temperature and pressure, by intensity measurements alone—provided, of course, that due regard is paid to any changes in shape or intensity that arise.

The high sensitivity which can be obtained with these methods can be applied to experiments where changes of dimension or angle are normally measured macroscopically.

Photomultiplier Studies of the Temporal Growth of Ionization during the Formative Time of Spark Breakdown in Nitrogen

The purpose of the present communication is to report the use of a photomultiplier technique to record the temporal growth of ionization in a pulsed Townsend discharge in nitrogen, with high values of the parameter pd (pressure × gap length) of ~1,000 mm mercury cm. The object of the investigation was to examine the

secondary ionization processes leading to the sparkover of uniform-field gaps, and to test current growth theory[1] under the aforementioned conditions, where the formative time lags are of the order of microseconds at low overvoltages and evaluation of the growth constant λ[1] requires measurement of the rate of growth of the discharge for currents up to 10^{-5} amp at which space-charge distortion becomes important.

A previous investigation in which formative time lags and transient current growth were measured simultaneously was confined to low values of pd (< 15 mm mercury cm), with a small pulse voltage superimposed on a static approach voltage of up to 3 kV (ref. 2): under these conditions the capacitance charging current flowing in the gap on application of the voltage pulse would be small, and the discharge current could be measured using a resistor in series with the gap. In the present work, in order to satisfy the condition that there should be no initial current in the gap[1], full impulse voltages of up to 50 kV were applied to the uniform-field gap; these had a rise time (10–90 per cent) of 0·2 μsec and time to half value of 500 msec. Consequently, the gap capacitance charging currents had peak values of the order of 1 amp. This, and the much faster growth of ionization obtaining at high values of pd, made direct measurement of the discharge current extremely difficult, and an alternative technique for measurement of the growth constant λ by observation of the radiation from the discharge was used.

Photomultipliers have been used in observations of individual avalanche pulses using static voltages close to the breakdown voltage, and it has been shown[3] that the rise of the electron current recorded by this means is identical with that recorded by the current measurement technique. In the present experiments, the output of the photomultiplier would therefore be proportional to the electron component of the discharge current and, as only the time constant of the current growth was required, calibration of the optical system was unnecessary.

The photomultiplier tube (EMI type 6256S) was mounted outside the glass discharge vessel about 50 cm from the centre of the discharge gap. Suitably placed screens shielded the tube from the light from an ultraviolet lamp used to irradiate the cathode and eliminate statistical time lags. The outputs from the photomultiplier and applied impulse voltage divider were viewed simultaneously on a double-beam oscillograph.

In measurements of the growth constant λ, the photomultiplier was operated at 1,000 V, and the temporal growth of ionization was seen as a smooth exponential curve from which accurate measurements could be made: typical records are shown in Fig. 1. Records were taken at several overvoltages, using various sensitivities on the oscillograph; the corresponding formative time lags (t_f) lay in the range 1·5–15 μsec. The output of the photomultiplier was of the order of 15 V at the end of the formative time, and sensitivities of 0·2–5 V/cm were used, the lower limit being set by the certainty with which the

($d = 3·0$ cm, $p = 200$ mm mercury, $\Delta V = 2·9$ per cent, $\lambda = 9 \times 10^6$: Oscillograph sensitivities were as indicated, ●, 5 V/cm; ×, 2 V/cm; ○, 1 V/cm)

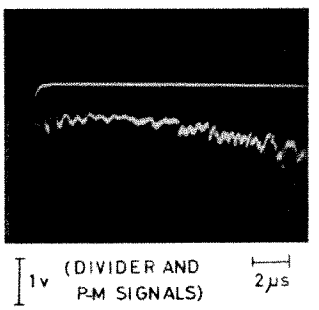

Fig. 3. Oscillogram of photomultiplier output at high sensitivity, showing individual electron avalanches in the early stages of the discharge current growth. Photomultiplier tube voltage, 1,500 V

mean signal could be determined, and the upper by saturation of the photomultiplier circuit.

The records were replotted on a logarithmic scale, and the growth constant evaluated at various overvoltages (ΔV). The accuracy with which λ may be determined depends on the amplitude of the noise superimposed on the growth signal and, with the photomultiplier technique, the output voltage was high enough at gap currents well below space-charge distortion level for measurements to be made at different sensitivities over several orders of magnitude. Fig. 2 shows results from three records for a time lag of 2·0 μsec, obtained at different sensitivities, and plotted to give a composite growth curve over three orders of magnitude. It is seen that the growth is exponential, giving a well-defined value of λ even for very short time lags which could be especially difficult to examine with the electrical technique. The values of λ thus obtained in nitrogen were found to be in excellent agreement with those calculated from ionization data measured in the same system under identical conditions[4].

As formative time-lag calculations indicated that hyperexponential current growth commences at $\sim 10^{-5}$ amp, and as the records obtained were sensibly exponential and referred to times $< 0·8\ t_f$, it is considered that this technique enables the growth constant to be measured when the discharge current is increasing in the range 10^{-9}–10^{-5} amp, compared with a lower limit of $\sim 5 \times 10^{-7}$ amp for the current measurement technique[2].

When the photomultiplier was operated at 1,500 V, the increased sensitivity enabled individual electron avalanches to be recorded in the early stages of the discharge current growth as shown in Fig. 3. If statistical effects were eliminated by providing initiating electrons by means of an α-particle, or short-duration pulse of ultra-violet light, such measurements would be useful in investigations of the earliest stages of impulse breakdown, and could be related to the exact solutions for the temporal growth of ionization[5].

This research was supported by the Central Electricity Research Laboratories and by a special grant from the Science Research Council. One of us (O. F.) is also grateful to the Science Research Council for the award of a research studentship.

Negative Temperatures

RECENTLY[1], through mapping the relation:

$$T \leftarrow e^{\psi} \qquad (1)$$

where $\psi = \int g(\theta)d\theta$ and depends on the thermal properties (θ) of the system, a relation was presented between the linear (Kelvin) and exponential thermodynamic temperature scales. It was shown through relation (1) that the absolute zero, $T = 0°$ K, is an inaccessible limit in the linear Kelvin temperature scale[1] defined by the asymptotic behaviour of its own explicit argument, the integrating factor[2], e^{ψ} ($\psi = -\infty$).

As a further consequence of the presented relation (1) it follows that if the so-called 'abnormal' negative energy thermodynamic states are admitted (Fig. 1) introducing negative temperatures[3–6] only the linear Kelvin temperature scale permits an extension, that is, formation of continuous sequence of numbers:

$$+0°\text{K} \ldots +273{\cdot}16°\text{K} \ldots \pm\infty°\text{K} \ldots -273{\cdot}16°\text{K} \ldots -0°\text{K} \qquad (2)$$

including both the positive and negative temperatures.

Thus, the acceptance of an equivalent exponential temperature scale (right-hand side of relation (1)), based on thermal properties of the system as shown by Caratheodory[2] in defining the integrating factor e^{ψ}, contradicts in effect the recently established existence of negative temperatures[3–6]. As a matter of fact, the exponential scale makes it possible to describe only the left-hand side of Fig. 1, with temperature, T, where T is defined:

$$T = \left(\frac{\partial S}{\partial E}\right)^{-1}_{X_i} \gtreqless 0 \qquad (3)$$

where X_i is any thermodynamic property, and $i = 1 \ldots k$.

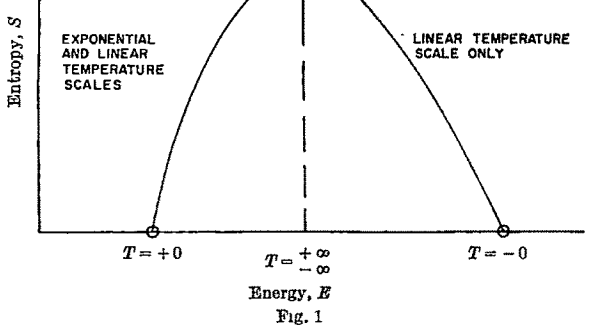

Fig. 1

This contradiction is real, and although no apparent violation of the Second Law of Thermodynamics is brought about by the introduction of negative temperatures—that is, negative energy states[7]—the existence of such 'abnormal' thermodynamic states is of a somewhat artificial nature, for they occur only in special subsystems. That this is so is evidenced by the experiment in which a change from positive to negative temperatures was achieved in an ingenious way which did not correspond to any ordinary reversible process[3–4].

We thank the National Research Council of Canada for financial assistance.

Observations of Power Station Plumes using a Pulsed Ruby Laser Rangefinder

As part of a comprehensive investigation of the dispersion of chimney gases from a power station, we have been much concerned with studying the behaviour of the buoyant plume during its initial rise. In order to understand its behaviour it is also desirable to have some knowledge of the atmospheric thermal structure. Since plumes from modern power stations are commonly too tenuous for optical observation and rise to heights above the range of convenient surface-based temperature sounding techniques, it has been necessary to develop new techniques. Collis *et al.*[1,2] have already pointed out the value of the pulsed ruby laser rangefinder for studying the atmospheric aerosol.

The necessity of detecting tenuous plumes well away from their source, coupled with the necessity simultaneously to detect the stable layers which profoundly influence plume behaviour, led us to investigate the use of the pulsed ruby laser rangefinder as a tool in pollution investigations.

Observations were made on July 6, 1965, at the 360-MW Tilbury power station with the prototype pulsed ruby laser rangefinder described in Table 1. A series of probes was made through the plume at five angles of elevation from 30°–10°, at 1-min intervals, on a constant bearing of 070° T. Oscilloscope traces from three of these probes are shown in Fig. 1. The regions of enhanced backscatter due to the plume have been marked. The envelope of the plume deduced from the series of probes is shown on a vertical section in Fig. 2. The pulsed ruby laser rangefinder is set up some 200 m from the stacks of the power station. The plume was emitted at a height of 100 m, and its axis intersected the section obliquely at a range

Table 1. G. AND E. BRADLEY PROTOTYPE PULSED RUBY LASER RANGEFINDER (1964)

Laser: 17 cm × 1·3 cm, 60°/C-axis ruby crystal (water cooled). Passive Q-switch using kryptocyanine solution.
Pulse length: 20 nsec
Peak power: 200 MW.
Beam width: 1·5 mrad.
Receiver: 20-cm diameter reflecting telescope with 5-mrad field of view.
Detector: Eleven-stage EMI photomultiplier 9558C.
Receiver bandpass: 20 Å.

of about 1 km. The wind speed was 5 msec^{-1}. The top of the plume has levelled out abruptly at a height of 600 m. From Fig. 1, it is apparent that the character of the environmental aerosol also changes abruptly at this height. Below 600 m the signal shows rapid fluctuations of the order of 10 per cent or more of the mean signal. Above 600 m the fluctuations do not exceed 2 per cent. This transition is strongly indicative of a stable layer overlying the adiabatic mixing layer. The rise of the plume had evidently been limited by this stable layer.

It should be emphasized that the tenuous plume was barely visible to the eye at the time of these observations, even though there were portions scattering up to ten times as much light as the environmental aerosol. The threshold of detection of a plume is clearly determined by the concentration and variability in the environmental aerosol, but we have found that plumes which scatter only 50 per cent more than the environment are normally detectable. The present equipment is capable of detecting such plumes at ranges of several kilometres.

Although the observations that have been described are of a single plume, we often observe up to four separate plumes on a single section from our pulsed ruby laser rangefinder. The sources vary in height from 60 m to 150 m,

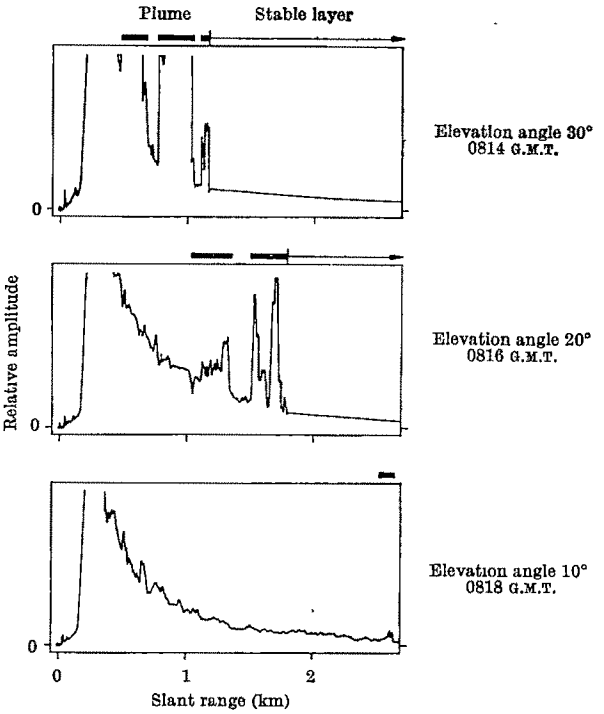

Fig. 1. Pulsed ruby laser rangefinder probes through Tilbury plume, July 6, 1965

and we have been able simultaneously to monitor the quite different behaviour of these plumes under changing atmospheric conditions. This is yet another aspect of the power of pulsed ruby laser rangefinders in pollution research, which judging from the present results will prove to be a powerful and versatile tool.

Size Analysis in the Sub-sieve Range by Electronic Counter

RECENTLY, Harris and Jowett have discussed an inherent shortcoming of the electronic counter which is able to count only those particles above a certain threshold size[1]. Thus a substantial portion of the sample remains unmeasured and in order to express the results by a conventional cumulative percentage, it is necessary to know the total amount of material in the suspension being counted. The authors point out that this could, in principle, be done gravimetrically, but reject this idea as unsuitable, remarking that "one of the potential advantages of the Coulter counter is that, in the suspension prepared for analysis, the concentration of solids need not be known; additionally, the gravimetric analysis would have to be highly sensitive". They go on to discuss several statistical methods for estimating the volume of solids that lie below the threshold of measurement of the counter.

Because we have been confronted by the same problem in our laboratory, we think it pertinent to describe our solution to it. We have found that the falling-drop method of determining the density of small amounts of solution or soil suspensions is admirably suited to the purpose.

A small sample of known volume is drawn from the suspension to be counted and injected into a column of an immiscible liquid with a density slightly less than that of the suspension. If the particles are suspended in water, the organic liquid anisole ($C_6H_5OCH_3$) is most suitable. The drop slowly sinks and, after the terminal velocity has been obtained, the time required for it to fall a specified distance is measured. The terminal velocity of a drop falling in such a system is a function of the difference in density between the drop and the liquid, according to an equation of the type established by Stokes. By comparing the measured time with times observed for drops of identical size, but consisting of salt solutions of various concentrations (and known densities), it is easy to find the

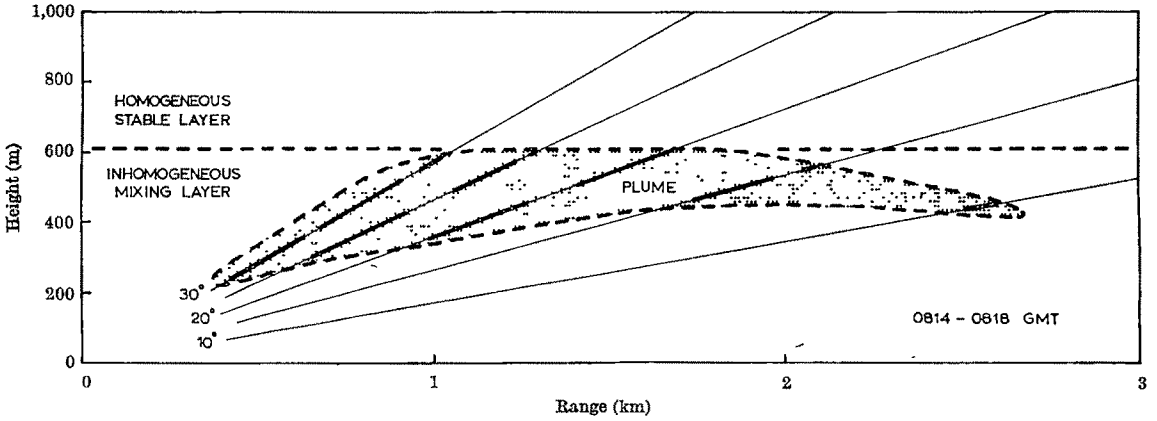

Fig 2. Vertical section from pulsed ruby laser rangefinder probes, Tilbury, July 6, 1965

average density of the drop of suspension. If the particle density is known, the particle concentration of the suspension is then easily computed, either by weight or volume. The calibration procedure makes it unnecessary to know the precise volume of the drops—so long as they are identical—and if drops of standard density are interspersed with 'unknowns' during a series of analyses, temperature and shape corrections to Stokes's law are avoided. The determination requires less than a minute per drop. Density measurements performed in this manner are usually accurate to the fourth decimal place—based usually on the observed mean of three drops. The error introduced by small differences in the volume of the drop is small; using a drop size of about 40 mm^3, the necessary accuracy is ± 1 mm^3 in order to obtain reliable results.

As the determination is simple and rapid, the falling-drop method can easily be applied to the complete grain-size analysis by sedimentation velocity procedures, and the method can be used to determine the density versus depth and time function in a sedimenting column with convenience and precision.

GEOLOGY

Permanency of Continents and Ocean Basin Lineations

Carr[1] recently proposed that the close correspondence between lineations on continents and the ocean floor and a theoretical shear net calculated by Vening Meinesz[2] militates against the hypothesis that the continents have drifted since Pre-Cambrian time. The long linear sea floor fracture zones, all discovered since Vening Meinesz drew his net, are admirably suited for testing such a correspondence. Some appear on the charts used in Carr's investigation, but many newly discovered ones do not. The whole pattern of fracture zones does not show a significant correlation with the shear net.

The Mendocino and Murray fracture zones follow the shear net in a very remarkable way[3], but they are only two of a vast system of sub-parallel and relatively evenly spaced fracture zones extending to the south. The Molokai, Clarion, Clipperton, Galapagos, Marquesas, and Easter fracture zones[4] have the same westerly to south-westerly trends across an enormous area of the eastern Pacific spanning 60 degrees of latitude. In the same region, the Vening Meinesz shear net changes direction by about 90 degrees. A two-step migration of the poles was capable of explaining the trend of the first four zones discovered[3], but it is not adequate to produce the pattern now known.

Numerous fracture zones have also been discovered in the Atlantic Ocean basin[5]. Almost all trend roughly west. The shear net, on the other hand, trends every direction in the Atlantic, and the only westerly trends are in high northern latitudes. Considering that the intensity of shearing is supposed to be at a maximum in the equatorial Atlantic, the total lack of correspondence appears crucial.

Fracture zones are also common in the Indian Ocean basin[6] where the intensity of shearing should be weak. Some follow the shear net and some do not.

In sum, the Vening Meinesz shear net shows a close correspondence with the margins of continents, but this is scarcely surprising because it was drawn to do so. It shows little correspondence with the whole pattern of enormous faults discovered on the sea floor during the past 15 years. It appears that this net should be allowed to rest in peace. What could be fruitful would be further application of the pioneering ideas and techniques developed by Vening Meinesz for the analysis of global shear patterns resulting from possible changes in speed of rotation and polar wandering indicated by geophysical data.

Global Network of Mobile Belts

Prof. J. Tuzo Wilson[1–3] has suggested that mountains, mid-ocean ridges, and major horizontal shear faults are not isolated features, that few come to dead ends, but that they are connected into a continuous network of mobile belts around the Earth which divide the surface into several large rigid plates.

This communication directs attention to a possible continental continuation of the network, based on the interpretation of the British–Scandinavian Caledonian chain[4–5], and the Mediterranean and Persian Alpine mountains as narrow mountain systems[6].

According to new investigations, the graben zones of the British–Scandinavian Caledonian chain (Fig. 1) originated as horizontal shear faults, caused by the main Caledonian stress[7]. The horizontal movements continued in post-Caledonian time, but as a result of epeirogenic Hercynian and Alpine movements between the blocks[8]. These movements have given the fault lines their character of graben zones.

With regard to the Alps, de Sitter[9] has concluded that in origin the Rhine trend and the Hercynian trend are a simple conjugate set of wrench faults, brought about by the Alpine stress.

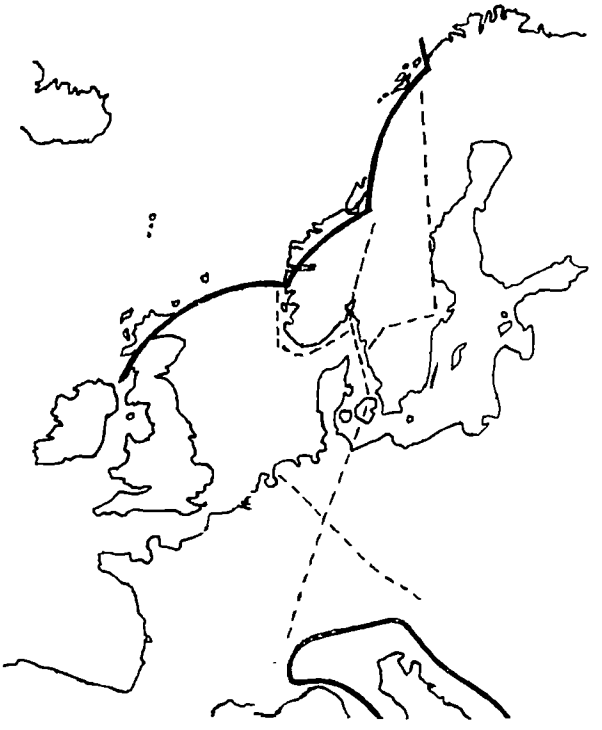

Fig. 1. Connexion between the graben zones of the British–Scandinavian Caledonian and the Mediterranean Alpine narrow mountain systems. Heavy lines represent axes of primary arcs and dashed lines fracture zones

An important feature is the connexion between the major fault lines in Europe[10]. They form continuous fracture zones between the hinterlands of the mountain systems, they have repeatedly been exposed to fault movements, and they terminate between the primary arcs (Fig. 1).

The fracture zones in the forelands are mainly submarine. They tend to terminate near the junctions of the primary arcs. The position of the partly continental fracture zones in the foreland on both sides of the Persian primary arc[1] supports this view. The conclusion seems warranted that they represent a continuation of the fracture zones in the hinterlands.

According to this interpretation, the junctions of the primary arcs form important cross-points between the mobile belts of mountain chains and major faults.

Orogenic Belts of the Northern Uganda Basement

THE Tectonic Map of Africa is being revised. It is appropriate, therefore, to direct attention to certain conclusions, produced at the second Symposium on African Geology held in March 1965, at Bedford College, London, regarding the status of previously established orogenic belts in the Northern Basement of Uganda.

Holmes[1] postulated the 'West Nile orogenic belt' after the predominant north-north-easterly trend of the gneissose rocks occurring in the district of that name in Uganda. He supposed that in the north the belt is either terminated by, or swings around to join the north-westerly trending Chua and Madi belts of de la Vallée Poussin[2] and Combe[3], respectively. Holmes further postulated that to the south the West Nile belt 'disappeared beneath' the 'Kibale-Toro' rocks.

Cahen[4] later used the term 'La formation du Nil occidental' for rocks in the Congo Republic which underlie the Kibalian and which are continuous with the gneisses of West Nile.

The existing Tectonic Map of Africa[5] places the West Nile rocks in the division 'Precambrian I Anterieur a 3 milliards d'années'. The Chua belt is not shown.

Mapping in West Nile by Hepworth[6,7] and Macdonald[8] has in part confirmed and in part modified Holmes's postulates. Thus Macdonald recognizes the north-westerly trending, Madi folding in the north of the district as a late tectonic event, and Hepworth has shown that in the south rocks of Kibalian trend are unconformable on, and of lower metamorphic grade than, the north-north-easterly striking rocks which they overlie. Although the axial trends of the Kibalian and Madi folds are similar they affect rocks of different groups and there is no evidence that they are the same age.

In the country which lies between these north-westerly trending belts in West Nile we have established three main tectonic groups. These are distinguished by characteristic structural styles, axial trends and metamorphism, and each may be orogenic in status. Macdonald has named them the 'Watian', 'Aruan', and 'Mirian'. The earliest, or Watian, is characterized by an east–west axial fold trend and a charnockite–granulite facies, partly anatectic metamorphism. This group has been retrogressively metamorphosed and partially re-worked in the ensuing Aruan tectonism. A time break between the Watian and Aruan is indicated by a dyke phase in the Watian which is absent in the other groups, or is represented by amphibolites in re-worked Watian rocks. The Aruan folds plunge gently north-north-easterly with steep axial planes and are associated with amphibolite facies metamorphism. The north-north-easterly axial trend of the Aruan and re-worked Watian rocks is the dominant structural direction in western and southern West Nile. The third tectonism, the Mirian, is characterized by recumbent isoclinal folds overturned from the south-east and south-south-east with flaggy axial plane cleavages and epidote–amphibolite facies metamorphism. This tectonic group is predominant in the north and east of the district.

Throughout much of the district the flaggy Mirian folding is succeeded by a fourth tectonic event with folding on north-westerly trending axes. Macdonald has shown that these folds, which in the north pass locally into mylonitic shear zones, increase in amplitude towards the Madi belt with which they are approximately co-axial, and so refers to them as 'Madian'.

In southern West Nile the Watian and Aruan rocks are cut by structural belts of tightly folded and foliated rocks with thick mylonites in the middle. Hepworth has termed these 'Refoliation Zones' and considers that they are the depth equivalent of the Mirian. He has pointed out that, although there is a difference of direction (north-east and north-west, respectively) and perhaps age, there is a strong structural resemblance between these 'Refoliation Zones' and the Aswa Zone.

In north central Uganda the Madi belt is continued south-eastwards by the Aswa Zone. This consists of a 6-mile-wide belt of strongly-foliated Basement rocks tightly folded on gently north-westerly plunging axes. The cover rocks of the Madi belt in West Nile are absent. The middle of the belt is mylonitic. A late kinematic granite extends for 30 miles along the northern part of the Zone. Some of the mylonites are refolded to form steep southward-plunging minor folds and these, together with a displacement of the granite by related cross-faults, indicate a late stage of transcurrent movement.

We propose to use 'Chuan' as a general term to include the Madian of West Nile and the Aswa Zone deformation, following Holmes's use of the name especially in his 'provisional map of the Pre-Cambrian orogenic belts of . . . Africa'[1].

Macdonald's[9] work in Karamoja, north-eastern Uganda, showed a suspected three-fold tectonic grouping with mylonitic shear zones which is remarkably similar in structural style and metamorphism to that now established in West Nile. The third group in apparent age in Karamoja, represented by the Flaggy Moroto Granulites and the Karasuk Group, is of similar style and lithology to the Turoka Series of Kenya and the Kenya 'Basement Complex System' in general and may correspond to part of the geosynclinal sediments of the Mozambiquian orogeny. At the same time, this third group in the Karamoja area strongly resembles the Mirian of West Nile in structural style and metamorphism.

Isotopic potassium/argon age determinations of micas from a Watian charnockite and an Aruan quartzite in West Nile give ages of 541 ± 22 m. yr. and 659 ± 26 m. yr., respectively[10]. These are ages of Mozambiquian range. As it is now known that the 'West Nile belt' comprises rocks affected by several orogenic events, the question arises as to which one is responsible for these apparent ages. Both the Aruan and Mirian produced pervasive metamorphisms in West Nile and the Chuan tectonism was also effective in northern West Nile and north-central Uganda. Thus the apparent age might be related

Table 1. TECTONIC EVENTS IN NORTHERN UGANDA

Southern West Nile	Northern West Nile	Aswa Zone	East-central Karamoja	
[KIBALIAN]← Relationship not known →MADIAN		CHUAN		
Folds trending NW No associated mylonites	Folds trending NNW–NW Mylonites trending approx E–W	Folds trending NW Mylonites trending NW		
MIRIAN Overthrust folds with NE–ENE axes			Kerasuk Group	? MOZAMBIQUIAN
Mylonites in 'Refoliation Zones' of the 'foreland' area, trending ENE	No evidence for mylonites in 'foreland' areas	(Note resemblance between southern W.N. 'Refoliation Zones' and Aswa Zone)	Flaggy Moroto Granulites Mylonites in 'foreland' area	400–650 m. yr.
ARUAN Folds trending N or NNE		Northerly trending gneisses cut by the Aswa Zone	Central Karamoja gneiss tectonism	? ?
WATIAN Folds trending E–W		Present as reworked granulites	Chernockite Group tectonism	? DODOMAN

to any of these tectonisms. It seems likely, however, that the Mirian, as expressed by the flaggy refoliated gneisses throughout the district and by the 'Refoliation Zones' in the south, was the dominant tectonism which imposed a Mozambiquian age on Aruan and Watian rocks. This correlation is perhaps supported by the strong tectono–metamorphic resemblance between the Mirian and the 'Mozambiquian' rocks in Karamoja. It is suggested that the Mirian may represent an early phase of the Mozambiquian and that the Chuan is a later phase, the age range of the Mozambiquian (*c.* 400–650 m. yr.) being enough to span both events (see Table 1).

If these suggestions are correct the 'pervasive event' invoked by geochronologists for the ubiquitous Mozambiquian ages in the African Basement acquires an identity as far as northern Uganda is concerned in the form of the Mirian and Chuan orogenies. The presence of granites in the Aswa Zone part of the Chuan lends support to this supposition.

As a result of these studies several considerations arise:

(1) The 'West Nile orogenic belt' is not a valid entity as it consists of four tectonic elements, the Watian, Aruan, Mirian and Chuan. Its status on the revised tectonic map should be reconsidered.

(2) The Chuan orogenic belt, which was omitted from the 1958 tectonic map and which crosses the West Nile belt, should be re-instated. If it is not sufficiently known from ground mapping it is now possible to delineate its extent by photogeological means.

(3) The Mozambiquian orogeny pervaded irregularly the 'foreland' of the northern Uganda Basement and is probably equivalent in age to the Chuan and Mirian tectonisms. This 'foreland' to the Mozambiquian, which is made up of congealed earlier orogenic belts, was thus fragmented by the Mozambiquian movements.

Recrystallization of Mica in Crenulated Schists

DR. NICHOLSON, in his recent communication[1], quite rightly states that in strain-slipped phyllites micaceous minerals commonly concentrate on alternate limbs of crenulations. This observation has been made by Clough[2] and repeated by King and Rast[3]. In my more recent paper[4] I was essentially concerned with the mechanics of growth of isolated matrix mica flakes under conditions involving annealing recrystallization, and not with the mechanism of chemical transport involved in chemical differentiation, which will be attempted elsewhere. My point, however, that in mimetic recrystallization mica flakes grow so as to become stain-free is amply illustrated by Dr. Nicholson's photographs. In particular his Fig. 2 shows clearly the completely stain-free mica flakes at the closures of microfolds. My other point that at a subsequent stage of recrystallization mica flakes grow parallel to axial planes of folds is again shown by Dr. Nicholson's Fig. 1. At no stage in my discussion did I claim that abundant new mica grows along the axial plane, but I did point out mica flakes growing parallel to axial planes. As my Fig. 4*d* shows, these micas, like Dr. Nicholson's Fig. 1, grow on the limbs of microfolds.

I have no objection to the explanation of quartz migrating from one site in the strain-slipped fabric to another, and I think his is an idea worth stating.

N. RAST

Department of Geology,
University of Liverpool.

[1] Nicholson, R., *Nature*, 209, 68 (1966).
[2] Clough, C. T., in *Geology of Cowal, Mem. Geol. Surv. Scotland*, 9 (1897).
[3] King, B. C., and Rast, N., *Geol. Mag.*, 93, 191 (1956).
[4] Rast, N., in *Controls of Metamorphism*, edit. by Pitcher and Flinn, 89 (1965)

DR. RAST'S letter is best answered by using his own text[1] which proceeds as follows. "Thus the first stage of [annealing] recrystallization . . . is . . . the regeneration of mica with approximate . . . orientation of the micas involved in the flexure. This regeneration . . . involves a nucleation step. It is an elementary assumption that where flexure of first generation micas is most intense the second generation mica will nucleate more rapidly [than elsewhere]. Assuming . . . initial post-nucleation growth is [the] most rapid, *it is likely that the points of maximum flexure will be the positions of maximum growth of phylloblastic minerals thus producing the phenomenon of metamorphic differentiation* (Fig. 4*b*). . . ." (My square brackets and italics.)

Thus Dr. Rast's text suggests this differentiation is a product of annealing recrystallization while I argued in my communication[2], largely on petrographic grounds, that it is produced during deformation. Since that

communication was written a modern petrological account of the south-west Highland rocks described by Clough[3] has been published[4] and in it there is a very interesting survey of the experimental information on quartz solubility which supports a view supposing silica mobility during deformation rather than the mobility of the components of mica. Secondly, it is difficult not to read the quotation as directly implying mica concentration along axial planes (taking the axial plane to be the surface joining 'points of maximum flexure'[1]). It is true that the caption to Dr. Rast's Fig. 4*b* (ref. 1) does refer "to concentration of mica on the limbs of microflexures", but this arrangement is referred to only once and then indirectly in the quotation given here where it seems to clash with the sense of the text.

I agree that my Fig. 2*b* (ref. 2) shows strain-free micas on fold hinges and this might well be a product of annealing recrystallization; this is not to say that this process produces differentiation. Fig. 1 of my communication[2], contrary to Dr. Rast's suggestion, does not show micas with cleavage and length parallel to fold traces. Instead it shows a schistose fabric continuous from a high mica concentration in one fold limb to a much lower concentration in the adjacent limb. As Dr. Rast observes, this has been described on many occasions, one recent example being in Prof. De Sitter's text-book, *Structural Geology*[5].

CHEMISTRY

Oxidation of Gaseous Formaldehyde

IN their investigation of the oxidation of gaseous formaldehyde at 337° C, Axford and Norrish[1] found that the reaction, which started immediately, was accompanied by a pressure increase. The rate of pressure rise gradually diminished as the reactants became consumed. The major overall reactions were considered on the basis of product analysis to be:

$$2H_2CO + O_2 \rightarrow 2H_2O + 2CO \quad (1)$$

and

$$H_2CO + O_2 \rightarrow H_2O + CO_2 \quad (2)$$

with the former predominating. The propagation steps, as suggested then and modified later by McKellar and Norrish[2], were:

$$CHO + O_2 \rightarrow CO + HO_2$$
$$HO_2 + H_2CO \rightarrow H_2O + CO + OH$$
$$OH + H_2CO \rightarrow H_2O + CHO$$

which together are equivalent to reaction (1). To explain the production of carbon dioxide the following step was postulated:

$$CHO + O_2 \rightarrow [HCO_3] \begin{cases} \rightarrow CO_2 + OH \\ \rightarrow CO + HO_2 \end{cases}$$

Recently, we have found that if the reaction vessel is allowed to mature from run to run and not treated with hydrofluoric or nitric acid between reactions, a delay develops in the attainment of maximum rate of pressure rise. During this stage and later we find considerable quantities of hydrogen peroxide are produced indicating that the reaction:

$$H_2CO + O_2 \rightarrow CO + H_2O_2$$

which proceeds without change of pressure, has been occurring. A cylindrical quartz reaction vessel which had been used for ethylene oxidations for several months without treatment was used for oxidizing a mixture of 100 mm formaldehyde and 200 mm oxygen at 320° C. In this, the hydrogen peroxide which formed rose to a maximum of 70 mm after the reaction had progressed for 30 min implying a 70 per cent conversion of formaldehyde to hydrogen peroxide, while the total pressure had only risen 8 mm. Over a period of several hours the pressure continued to rise by a further 24 mm and the hydrogen peroxide finally disappeared.

New reaction vessels of quartz or 'Pyrex' previously washed with hydrofluoric or nitric acid gave completely different results closely approximating to the observations of Axford and Norrish. The rate of pressure rise was much greater; it commenced almost immediately at its maximum rate and less than 2 per cent conversion to hydrogen peroxide occurred. After three or four reactions had been performed the rate of pressure rise was decreased and its maximum rate delayed, and increasing quantities of hydrogen peroxide began to be formed. Washing the vessels again with nitric acid restored the original conditions of pressure rise and low hydrogen peroxide concentration, but merely evacuating between runs had no effect of this kind; a gradually increasing quantity of hydrogen peroxide was formed as maturing proceeded. In the quartz vessel this process seemed more rapid.

In the experiments of Axford and Norrish, a pressure of about 1 mm of mercury was present in the reaction vessel—due to the use of heated mercury cut-offs—and in repeating this work, Scheer[3] concluded that similar results could be obtained either by introducing mercury at this pressure or by cleaning the silica vessel with nitric acid before each run. On the other hand, use of a matured vessel gave results similar to ours in that there was a delay before the pressure rise reached its maximum rate. His analysis by mass spectrometry showed unidentified peaks with mass numbers in the range 30–95. He ascribed these to peroxides and in particular performic acid was tentatively identified by peaks at 62, 61 and 60. A mass spectrum of reaction products frozen out of our matured reaction vessel showed no such peaks, but we found a conspicuous peak at mass number 34 which we attributed to hydrogen peroxide. Scheer's mechanism for propagation of the reaction was:

$$CHO + O_2 \rightarrow HCO_3$$
$$HCO_3 + H_2CO \rightarrow HCOOOH + CHO$$

and these two steps are equivalent to:

$$H_2CO + O_2 \rightarrow HCOOOH$$

Final products were supposed to arise from decomposition of performic acid or by its reactions with more formaldehyde, but it is evident from the stoichiometry of the reaction that if performic acid is a true intermediate an initial pressure decrease would be observed, contrary to experience.

We have shown that a clean surface is very effective in destroying hydrogen peroxide as it is formed, whereas a series of reactions performed without treating the surface causes this to alter, becoming more inert so that the hydrogen peroxide concentration can build up. We consider that these results can be explained by the following propagation step which can be compared with those outlined above:

$$CHO + O_2 \rightarrow [HCO_3] \rightarrow CO + HO_2$$
$$HO_2 + H_2CO \rightarrow CHO + H_2O_2$$

The net result of these two steps is:

$$H_2CO + O_2 \rightarrow CO + H_2O_2$$

Decomposition of hydrogen peroxide occurs according to:

$$H_2O_2 \rightarrow H_2O + \tfrac{1}{2}O_2$$

Under the conditions which operate in a matured vessel, this last reaction is very slow so that the main course of the reaction proceeds with only a small pressure change. Subsequent decomposition of hydrogen peroxide causes the pressure to continue to rise slowly, though by this time most of the formaldehyde will have been oxidized.

Since the oxidation of ethylene and methanol gives rise to formaldehyde directly, we consider that large quantities of hydrogen peroxide should be formed in suitably conditioned reaction vessels when these substances are oxidized. Recently we have found a 20 per cent conversion of ethylene to hydrogen peroxide at 320° C in a matured quartz vessel. It seems probable that with flow methods even higher yields of hydrogen peroxide may be possible.

Factors affecting the Mobilities of Anions in Nylon

IT has been reported[1,2] that the diffusion coefficients of anions in nylon rapidly increase with increasing internal concentration. In the case of the trisulphonic dye naphthalene scarlet 4*R*, McGregor, Peters and Petropolous[2] attributed this result to a proportionality between the diffusion coefficient and some power of the activity coefficient of the anion. Atherton and Peters[3] modified the Gilbert-Rideal theory[4] (originally developed to explain the sorption of inorganic acids by wool) so as to cover polyvalent dyes in nylon; they obtained anion activity coefficients of the form $[1/(1-\theta_A)]$, where θ is the fraction of occupied amine sites.

We wish to direct attention to the importance of distinguishing between the influence on diffusion of direct interactions between anion and substrate, and interactions involving the accompanying cations (usually protons). These associate with specific sites in the nylon so that the proton activity coefficient takes the form $1/(1-\theta_H)$; if coupled bulk transport of dye acid occurs, proton activity variation leads to relationships between diffusion coefficient and concentration of the type observed. This effect can only be satisfactorily eliminated by using radiotracers, which enable anion mobilities to be measured. Even when this is done, there remains the possibility that anion mobility can be increased by co-operative interaction with mobile cations. Such effects have been observed in keratin[5]. For acid sorption, the number of free protons is $\theta_H/(1-\theta_H)$, so proliferation occurs near the site-saturation point, and gives rise to a similar experimental result.

The following tracer experiments illustrate these points. The ions investigated were a simple inorganic ion, Br^-, and a monosulphonic dye anion, naphthalene orange *G* (*NOG*, C.I. acid orange 7).

The internal concentration range investigated was the so-called 'amine-dyeing' region. The amine end group content, 0·028 m.equiv./g, was obtained by dissolving the nylon in 70 : 30 per cent phenol : methanol solution and titrating with N/20 hydrochloric acid solution using thymol blue as the indicator. The titration curve of each acid has a shoulder at approximately 0·026 m.equiv./g (at the temperature at which the diffusion runs were carried out), before rapidly rising at low *p*H's due to acid sorption on the amide sites.

It can be seen from Fig. 1*A* that the diffusion coefficient of the inorganic ion in the amine-dyeing region varies only slightly with internal concentration; it is impossible to explain in this case the variation of diffusion coefficient with concentration merely in terms of an idealized activity coefficient of the form $\frac{1}{(1-\theta)}$.

Two curves are shown for the NOG anion. Fig. 1*B*, curve *b*, at internal concentrations less than 0·02

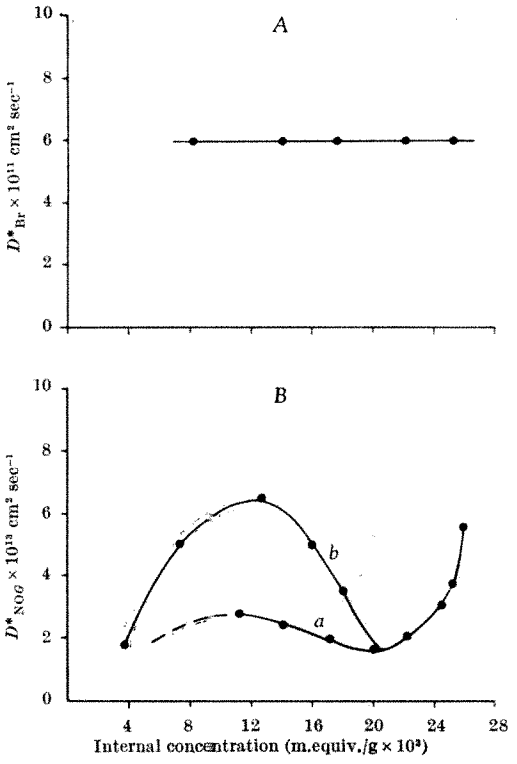

Fig. 1

m.equiv./g, was obtained using buffered solutions (buffer concentration M/100 mixed phosphate) whereas curve *a* was obtained under free acid conditions. Free acid points could not be obtained for internal concentration < 0·01 m.equiv./g since these correspond to external free acid concentrations of 10^{-6} N and lower. The general effect of the use of buffer is to produce a pronounced peak at an internal concentration of about 0·012 m.equiv./g.

In the absence of buffer, the height of the peak is reduced. It has been shown previously that the presence of inorganic electrolytes accelerates NOG in keratin and that even more pronounced effects are observed with polyvalent ions. The pronounced peak in the presence of buffer may well have a similar cause and it is, therefore, of considerable importance to exclude all ions other than those of the free dye acid from the system in investigations of this kind. After allowing for possible ion-acceleration effects, there remains the residual negative slope on curve *a* in the intermediate internal concentration range; such an effect was previously observed in keratin also[6], and was attributed to internal agglomeration. In view of this complex behaviour the $\frac{1}{(1-\theta)}$ term is inadequate at intermediate concentrations.

The dye self-diffusion coefficient increases rapidly with increasing concentration as the available amine sites become saturated ($\theta \rightarrow 1$) as was observed by Peters *et al.*[2] with naphthalene scarlet 4*R*. It remains to be seen whether this is solely due to interactions between the anion and the fixed positive sites, or whether interactions with the hydrogen ions also play a part, analogous to the salt acceleration effect already described.

Absorption Spectra of Excited Atoms and Excited Ions produced by Isothermal Flash Photolysis of Metal Carbonyls in the Gas Phase

SPIN-ORBIT multiplets of atoms in ground electronic states are particularly interesting for the investigation of electronic energy transfer; simple theoretical considerations indicate that the relaxation rates correlate with the magnitude of the internal energy changes[1]. Measurements of the formation and decay of excited selenium (4^3P) and iodine (5^2P) have already been reported[2,3]. We have recently shown that the flash photolysis of iron pentacarbonyl ($Fe(CO)_5$), which has been investigated in some detail, and of nickel carbonyl ($Ni(CO)_4$), can be used to produce excited atoms in gases under isothermal conditions. Spin-orbit relaxation rates can be measured by kinetic spectroscopy, before polymerization of the normal atoms occurs. The method is general to volatile transition-metal compounds, and the observations therefore reveal numerous experimental systems for energy transfer studies.

A flash-photolysis apparatus of standard design produced a 1700-J light pulse in 5×10^{-5} sec, and absorption spectra were recorded with a Hilger Medium Quartz Spectrograph. In experiments with $Fe(CO)_5$ at pressures of 0·005–0·001 mm of mercury, and argon added to a total of 10–50 mm of mercury, the disappearance of the far ultra-violet continuum of the carbonyl was complete in the first 3×10^{-5} sec of the flash. The absence of any significant rise in temperature may be shown by calculation, assuming each $Fe(CO)_5$ molecule to absorb five light quanta at 2000 Å, or else demonstrated experimentally by deducing the equilibrium concentration in the a^5D_4 and a^5D_3 states from the observed line intensities in absorption and the published oscillator strengths[4].

Table 1 shows the states of atomic iron detected in absorption in flashed $Fe(CO)_5$/argon mixtures. The energies correspond to the lowest of the spin-orbit multiplets[5].

The highly excited levels rapidly decay to populate the spin-orbit components of the a^5D state; relaxation of the a^5D multiplets occurs in 10^{-4} sec. The calculated temperature rise, the rapid decay of the excited atoms, and the increased rate of decay caused by addition of traces of polyatomic gases prove that the extent of electronic excitation is greatly in excess of a Boltzmann distribution at the translational temperature, which remains close to 300° K. (With partial pressures of $Fe(CO)_5$ of the order of 0·1 mm of mercury, relaxation is extremely fast and the population in the lower electronic states is due to a substantial temperature rise.) Provided the $Fe(CO)_5$ is completely destroyed by the flash, the populations in the a^5D states are independent of the energy of the flash, and the most highly excited distributions occur at the shortest delay times. Photodissociation evidently produces atomic iron in a range of electronic states, for example:

$$Fe\,CO + h\nu \rightarrow Fe^* + CO$$

Our original objective was to measure the rate of the $a^5D_3 \rightarrow a^5D_4$ (416 cm^{-1}) transition in argon, and the probability of deactivation has been recorded as $0{\cdot}2 \times 10^{-4}$ at 300° K. This is significantly slower than vibrational relaxation of non-hydrides, if the same energy is transferred to translation.

Flash photolysis of $Fe(CO)_5$ provides the first example of the production of ions in a gas at concentrations ($\sim 10^{12}$ ions/c.c.) suitable for measurement by kinetic absorption spectroscopy. Fig. 1 shows the formation and decay of Fe^+ (a^6D). The relative populations of the five multiplets

Table 1

State	Energy (cm^{-1})	State	Energy (cm^{-1})
a^5D	0	a^3H	19,360
a^5F	6,928	b^3F	20,641
a^3F	11,976	a^3G	21,715
a^5P	17,550	Z^7F	22,650
a^3P	18,378	b^3P	22,838
Z^7D	19,350	Z^7P	23,711

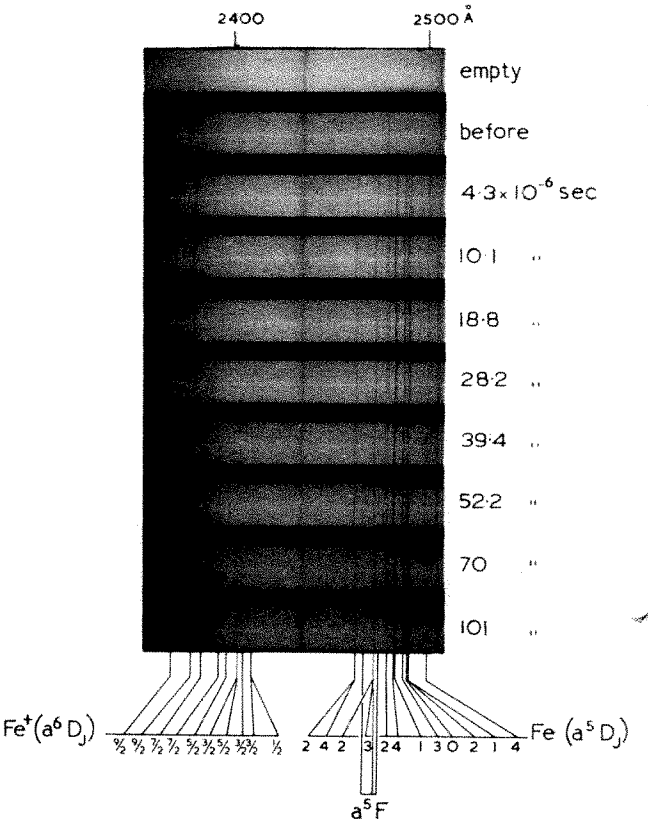

Fig. 1. Formation and decay of $Fe^+(a^6D)$ in flashed $Fe(CO)_5$ vapour

vary during and following the flash. We have also shown that the total concentration of ions increases linearly with flash energy. Ultra-violet radiation at the 1850 Å oxygen cut-off is 10,000 cm^{-1} short of the 7·40 eV ionization potential of atomic iron in the a^5D_4 state. However, all states above a^5F suffer ionization by secondary light absorption. The decay rate of the ions increases with increasing pressure, which may suggest that removal is by three body processes.

We have made preliminary measurements of the non-Boltzmann electronic-distribution of atomic nickel, produced by flash photolysis of $Ni(CO)_4$.

Dynamic Fatigue in Glasses

THE static fatigue of glasses is a well-known and well-documented phenomenon (see, for example, ref. 1), but the only investigation of cyclic loading fatigue known to the authors is that of Gurney and Pearson[2], who reported a negative result. Perhaps in view of this result and of the near ideal brittle behaviour of glasses the investigation of cyclic loading fatigue appears to have been neglected. Recent results obtained in these laboratories as part of an extensive investigation of the strength of fused silica have indicated that a real cyclic fatigue effect may exist in this material. Circumstances have prevented a full investigation and confirmation of the effect, but in view of the importance of the problem the preliminary results would seem worth reporting here.

In the upper part of Fig. 1 a comparison is made between the static fatigue life under constant tensile

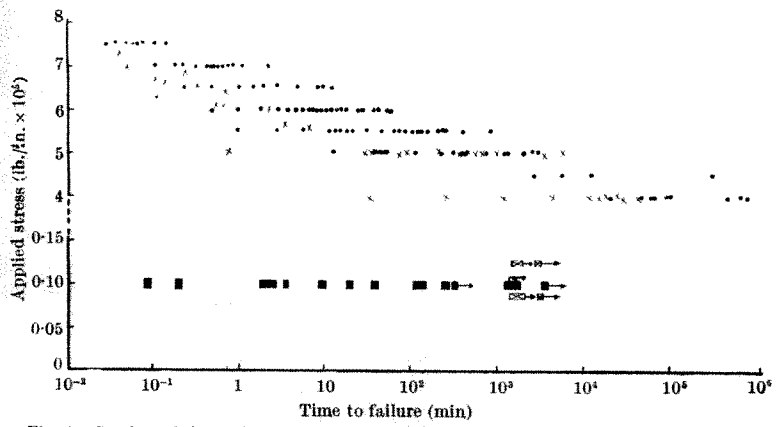

Fig. 1. Static and dynamic fatigue of silica. ●, Static fatigue of silica fibres in tension; ×, dynamic fatigue of silica fibres in tension; ⊠, static fatigue of silica rods in bending; ■, dynamic fatigue of silica rods in rotating bending. ■→ and ⊠→ indicate samples surviving life shown

stress, and the fatigue life under cyclic tensile stress, of virgin silica fibres[3]. The repetition rate of cyclic loading was in the range 30–75/min and the stress varied from zero to the nominal stress plotted on the graph. Loading was achieved by picking up and releasing a dead weight with a cam and the pulse shape was a flat-topped half sine curve so that stress was only applied to the fibre for less than one half the plotted times. Particularly significant are the early failures at 400,000 lb./in.^{2}.

In the lower part of Fig. 1 a comparison is made between static fatigue in cantilever loading, and rotating bending fatigue in cantilever loading, of mechanically damaged 1 mm diameter fused silica rods at much lower strength-levels. The cycling rate here was very much higher (3,700/min) and the cycle approximated to a full sine curve with the stress reversing from the maximum tensile value shown in Fig. 1, through zero, to the same value in compression. At the same stress and over the same time scale, no failures were observed with the comparable static bending fatigue specimens.

BIOCHEMISTRY

Acetylcholine-like Activity of Acetyl-l-carnityl CoA in the Brains of Narcotized Rats

Numerous investigators[1–5] have shown that the administration of narcotic drugs to animals causes an increase in the brain acetylcholine-like activity. Most of these authors[1–4] believed that the material extractable from such brains was acetylcholine and this was based largely on the results obtained from experiments performed with the parallel bio-assay technique. Hosein and Koh[6] and Hosein, Rambaut, Chabrol and Orzeck[7] have shown that the method of parallel bio-assay is incapable of identifying acetylcholine in mixtures of substances which possess acetylcholine-like activity. In addition, these latter authors showed that the various test preparations used in the method of parallel bio-assay could not discriminate between mixtures of substances which possessed acetylcholine-like activity, even when non-natural substances were used.

Hosein and his associates[8,9] have shown by microchemical analysis that, of the material with acetylcholine-like activity extractable with trichloroacetic acid from brain, 20 per cent of this activity was due to a mixture of choline esters and the remainder to a mixture of butyrobetaine CoA esters. Numerous investigators[10–13] have since performed chromatographic separation of similar brain extracts and, although the peak of acetylcholine-like activity on the chromatogram differed in each such attempt (range from R_F 0·05 to 0·9), in every instance it was concluded that the active material was due solely to acetylcholine. Recently, Maslova[14], in contradicting the findings of Birks and MacIntosh[15] while confirming those of Hosein and Proulx[16], has shown that chemically identifiable acetylcholine in trichloroacetic acid extracts of the superior cervical ganglia accounted for only one-fifth of the amount of such material determined by bio-assay.

Hosein and Ara[5] suggested, on the basis of chromatographic analysis of trichloroacetic acid extracts of narcotized rat brain, that the material with acetylcholine-like activity was probably a butyrobetaine CoA ester rather than a choline ester. Hosein and Koh[17] showed on the basis of chromatographic and chemical analyses that the material with acetylcholine-like activity extractable from narcotized brain was acetyl-1-carnityl CoA. The experiments described here represent an extension of this work.

Sixty rats were deeply narcotized with pentobarbital (65 mg/kg) for 30 min. After that time the animals were killed and the brains were homogenized (fifteen at a time) in 5 per cent trichloroacetic acid. This extract was prepared for bio-assay with the frog rectus preparation as previously described[5,8]. The total activity found in the sample was equivalent to 276 μg acetylcholine chloride which was then divided into two equal parts, *A* and *B*. A solution containing 138 μg of crystalline acetylcholine chloride was added to sample *B*. The two samples *A* and *B* were evaporated to dryness and then converted to their tetrachloroaurate derivatives[8]. In each sample there was material which formed an immediate precipitate with the auric chloride and which could easily be collected by centrifuging as crystals fraction (i). When the supernatant fluid of each sample was left in the refrigerator for a further period of 4–5 days, crystals fraction (ii) was collected. The substances in the various fractions were identified by melting-point determination.

The results obtained from such analyses are shown in Table 1. It can be seen that the added acetylcholine was readily recovered and identified in crystals fraction (i) of sample *B*. No such material could be found in the corresponding fraction of sample *A*. Crystals fraction (ii) of both samples *A* and *B* contained material that melted at 120°–124° C which, in other work, we have shown to be acetyl-1-carnitine[9]. It was observed in previous work that preparation of the tetrachloroaurate derivatives of the CoA ester of the butyrobetaines in tissue extracts destroys the thiol ester linkage. It was assumed that a similar reaction took place in this extract.

In these experiments a small amount of materials in crystals fraction (i) only was found to have a melting-point of 130° C. Hosein and Proulx (unpublished) have found that the tetrachloroaurate of γ-butyrobetainyl choline also melts at 130° C. Further chemical analyses are, however, required to identify these particular crystals.

Table 1. Melting Point Determinations of Tetrachloroaurate Derivatives present in Trichloroacetic Acid Extracts of Narcotized Rat Brains

Sample	Melting point (° C) of crystal fractions (i)	(ii)	Probable substance
A	—	120–124	Acetyl-1-carnitine
	130	—	(γ-Butyrobetainyl choline) ?
B	—	120–124	Acetyl-1-carnitine
	130	—	(γ-Butyrobetainyl choline) ?
	165–167	—	Acetylcholine

The results described above indicate that, if acetylcholine were the sole material with acetylcholine-like activity in the brain extract, then it would have been possible to isolate and identify it, as was done for the equivalent amount of added crystalline acetylcholine chloride. This was not observed. It is therefore unlikely that the original material could have been acetylcholine. The results obtained, however, strongly support the previous findings of Hosein and Koh[17] that the material with acetylcholine-like activity in narcotized rat brain extracts is probably acetyl-1-carnityl Co*A*.

Effect of Adenosylethionine on 5-Methyltetrahydrofolate-homocysteine Transmethylase

THE 5-methyltetrahydrofolate-homocysteine transmethylase of *Escherichia coli* requires catalytic quantities of *S*-adenosyl-L-methionine[1] and a vitamin B_{12} derivative for activity[2]. It was of interest to determine the effect of *S*-adenosyl-L-ethionine on this reaction since this compound can substitute for adenosylmethionine in certain enzyme-catalysed reactions such as the formation of the ethyl derivatives of phospholipid choline, creatine, histidine and carnosine[3,4]. Adenosylethionine bromide was isolated from rat liver after ethionine feeding[5]. It behaved as a single spot on a paper chromatogram with 1-butanol–acetic acid–water (60:15:25, v/v/v) as the solvent. After boiling in 0·1 N sodium hydroxide for 1 h a chromatogram of the digest yielded spots for ethionine, homoserine and adenine[5]. Adenosylmethionine iodide was purchased from Calbiochem, Los Angeles, Calif. It was found (Table 1) that adenosylethionine could not replace adenosylmethionine in the reaction under investigation. When added simultaneously at equal concentration little or no effect was observed. Significant inhibition was observed when adenosylethionine was pre-incubated with the enzyme or when higher concentrations of adenosylethionine were employed.

Table 1. EFFECT OF ADENOSYLETHIONINE ON 5-METHYLTETRAHYDROFOLATE-HOMOCYSTEINE TRANSMETHYLASE

Reaction mixture: *d,l*-L-5-methyltetrahydrofolate, 3·5 μmoles; D,L-homocysteine, 20 μmoles; DPHN, 1 μmole; FAD, 0·4 μmole; K_2PO_4 buffer, *p*H 7·4, 200 μmoles; 5-methyltetrahydrofolate-homocysteine transmethylase (partially purified from *E. coli* (ref. 2)), 2·7 mg; protein containing 150 mμg vitamin B_{12}. The total volume was 2 ml. Incubation was carried out at 37° C under hydrogen in Thunberg tubes for 1·5 h. Methionine was determined microbiologically with *Leuconostoc mesenteroides* (ATCC 8042). The assay was not affected by adenosylethionine.

Adenosylethionine (μmoles)	Adenosylmethionine (μmoles)	L-methionine (μmoles)	Inhibition (per cent)

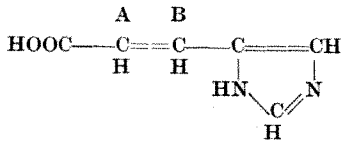
Trans to *Cis* Isomerization of Urocanic Acid



IRRADIATION of natural and synthetic urocanic acid with ultra-violet light results in the formation of a new product which has been identified by melting-point determination, ultra-violet and infra-red spectroscopy, and chromatography[1–3]. By analogy with cinnamic acid this has been thought to be a *trans* to *cis* isomerization. A similar change occurs in the urocanic acid of mammalian epidermis *in vivo* when the animals are exposed to ultra-violet light[4]. Using nuclear magnetic resonance it has been possible to demonstrate more conclusively that this ultra-violet-induced transformation is a *trans-cis* isomerization.

Commercial urocanic acid was shown by paper chromatography to contain trace amounts of a contaminant with the same R_F as the product formed by irradiation with ultra-violet light. A 0·1 per cent solution of urocanic acid at *p*H 6·0 was irradiated with stirring at 0° C with a General Electric sunlamp (1×10^6 ergs cm^{-2} sec^{-1}). Paper chromatography was performed on the concentrated solution in propanol and ammonia (3 : 1), and showed two spots with R_F values of 0·51 and 0·70—the former being identical to the major spot in the original material and the latter to the trace component. These compounds were separated by differential water solubility; their physical properties are shown in Table 1. Nuclear magnetic resonance spectra were obtained on a 10 per cent solution in deuterium oxide with a Varian *A*60 instrument. The chemical shifts of the doublets corresponding to the various olefinic protons and the spin–spin coupling constants are indicated. The structural assignments are based on the known effect of structure on the physical properties enumerated. Cinnamic acid, for example, shows a change in the coupling constant from 15·8 c.p.s.

Table 1

	R_F	M.p. (° C)	λ Max (mμ) at pH 1	Chemical shifts (p.p.m.*) HA	HB	Coupling constant c.p.s.
Trans	0·51	224	267	6·37	7·27	16
Cis	0·70	180–184	270	6·18	7·07	13

* Down field relative to 3-(trimethylsilyl) propylsulphonic acid (Na salt) as internal standard.

to 12·3 c.p.s. for the olefinic protons of the *trans* and *cis* isomers respectively[5]. It is of interest that the extinction coefficient of the *cis* isomer of cinnamic acid is much less than the *trans*[6], while those of urocanic acid are quite similar.

Because of the large amount of material needed for the nuclear magnetic resonance studies it was necessary to use isotope techniques to identify the new ultra-violet light absorbing product formed in epidermis following irradiation. Guinea-pigs were injected with 20 μc. of L-histidine-^{14}C (uniformly labelled) intraperitoneally and 24 h later they were depilated with wax and given a minimal erythema dose of ultra-violet light with a 'Hanovia' hot quartz lamp. The epidermis was separated by heating the skin to 50° C for 1 min and the urocanic acid isolated on a 'Dowex-1 formate' column as previously described[7]. Two radioactive compounds were identified by chromatography and autoradiography. The spots were eluted from the paper and chromatographed with the *cis* and *trans* isomers to which they corresponded exactly.

The data presented confirm that natural urocanic acid consists of the *trans* isomer contaminated with some *cis* and that following irradiation there is a *trans* to *cis* isomerization. This same reaction also occurs in the epidermis where urocanic acid is present at a high concentration.

Cortisone-induced Lipaemia and Hepatic Steatosis in the Male Rat

It has previously been reported that female rats develop lipaemia and fatty livers during treatment with cortisone[1], and, more recently, the pathogenesis of this has been traced to a markedly enhanced mobilization of fatty acids from adipose tissue[2]. The mechanism thus seems quite different from that accounting for the fat accumulation in the livers of female, but not of male, rats during ethionine administration[3], and it is not reversed or prevented by measures which are effective during ethionine treatment[2]. Nevertheless, it is important to clarify whether the effect could also be observed in male rats.

Male albino 190–200 g rats were treated in a manner identical to that used previously for female rats[1]. All rats received tube feedings three times daily of a liquid diet; control rats gained weight well (average weight 247 g after 3 weeks). Experimental rats received 6·25 mg cortisone intramuscularly daily, while controls received saline. The experimental rats lost weight (average weight 170 g after 3 weeks). Animals were killed after 3 weeks; serum and liver lipids were extracted and total glycerides estimated by the van Handel–Zilversmit procedure[4]. Liver protein content was determined on a saline homogenate by the method of Oyama and Eagle[5].

Results of lipid analysis are shown in Table 1. The magnitude of rise of serum and hepatic lipids is similar to that seen in female rats[1]. Thus, it seems clear that no sex difference can be demonstrated for the fatty acid mobilizing properties of cortisone.

In vivo Conversion of γ-Hydroxybutyrate into γ-Aminobutyrate

γ-Aminobutyrate (GABA) transaminates in normal brain to succinic semialdehyde[1,2] which in turn oxidates to succinic acid[3].

Moreover, Fishbein and Bessman[4] report that in the soluble fraction of brain homogenate, succinic semialdehyde is reduced to γ-hydroxybutyrate by action of a DPN^+ depending enzyme, indistinguishable from lactic-dehydrogenase; γ-hydroxybutyrate is then lactonized to γ-butyrolactone[5]. γ-Hydroxybutyrate and γ-butyrolactone have been recognized in large amounts in the normal nervous system and they seem the only physiological compounds in the nervous system which have an anaesthetic activity[6].

This communication reports on the variation of γ-aminobutyrate content in rat brain after injection of γ-hydroxybutyrate.

Male albino rats (200 g weight) were injected intraperitoneally with 500 mg/kg of γ-hydroxybutyrate. The rats were killed 2 h after injection and the brain removed and homogenized with 70 per cent alcohol (20 ml./g brain). After centrifugation and extraction with chloroform (10 ml./g brain), the alcohol layer was dried *in vacuo* at 40° C; the residue was dissolved with 1 ml. water/g brain.

γ-Aminobutyrate was separated by paper electrophoresis; 25 or 50 μl. of residue were utilized. Paper: Whatman No. 1; pyridine–acetic acid–water, buffer (250 : 50 : 900); *p*H 6, 12 V/cm, for 1·5 h. Paper strips, dried with hot air, were sprayed with 0·1 per cent ninhydrin in butanol (Fig. 1). A Chromoscan apparatus was used for reading the quantitative measurements. The standard curve

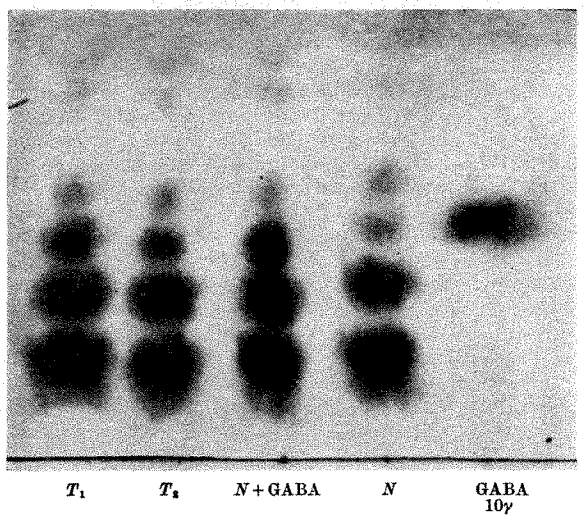

Fig. 1. Paper electrophoresis of rat brain extract (25 μl.). *N*, Control; T_1–T_2, brain of rat injected intraperitoneally with 500 mg/kg of γ-hydroxybutyrate, killed 2 h after injection; *N* + GABA, control + 200γ of GABA added per g brain wet weight after deproteinization

was made with known amounts of γ-aminobutyrate on the same paper.

The results of these measurements showed that after injection of γ-hydroxybutyrate, the γ-aminobutyrate content of rat brain rose from 2·2 to 3·0 μmoles/g brain wet weight (Table 1).

Table 1. γ-AMINOBUTYRATE CONTENT IN RAT BRAIN

	μmol/g wet weight
Controls	2·2
Rats treated with 500 mg/kg γ-hydroxybutyrate	3·0
Percentage increase	36·3

Absorption Changes in Blue-green Algae at the Temperature of Liquid Nitrogen

THE light-induced bleaching of a pigment at 700 nm in blue-green algae has been observed by many investigators, beginning with Kok[1]. It has been suggested that this absorption change is a manifestation of a primary photochemical event: the oxidation of a specialized chlorophyll component, perhaps the 'sink' of the long wavelength pigment system. In this connexion the behaviour of this change at low temperatures is important. Rumberg, Müller and Witt[2] and also Chance and Bonner[3] have reported the occurrence of an irreversible photo-induced decrease in absorption at 700 nm in chloroplasts maintained at the temperature of liquid nitrogen. On the other hand, Kok and Hoch[4] alluded to a reversible change at liquid nitrogen temperature. Data that show clearly the partial reversibility of the 700 nm change at low temperatures have not heretofore been published.

Measurements of absorption change on *Anacystis* and other organisms were made at liquid nitrogen temperature and at room temperature, using a commercial version of the Britton Chance dual wave-length spectrophotometer (Aminco, Silver Springs, Md.) modified by us to accept a small dewar with the sample. The photosynthetic material was held by capillary attraction between a microscope cover slip and a flat glass plate fused to the bottom of a 2·5 cm diameter test-tube. The test-tube fitted snugly in an unsilvered dewar[5]. The sample was cooled by conduction from liquid nitrogen placed in the test-tube above the sample.

Interference filters were placed in front of the photomultiplier to protect the detector from the actinic light and to reduce the various artefacts which may be observed in the absence of this precaution[6]. Further checks were made by comparing the results obtained with the photomultiplier close to the sample and also 15 cm away from the sample. Moving the photomultiplier away from the sample should greatly diminish the size of artefacts due to fluorescence while increasing artefacts due to changes in scattering. By these procedures, we concluded that the changes observed were due to absorption.

Experiments performed at room temperature followed closely the results reported by Kok and others[1]. At liquid nitrogen temperature, a reversible decrease in absorption at 705 superimposed on an irreversible change is observed on illumination. This is illustrated in Fig. 1. The ratio of the reversible to the irreversible component varies in different experiments but is about 1 : 1 for the

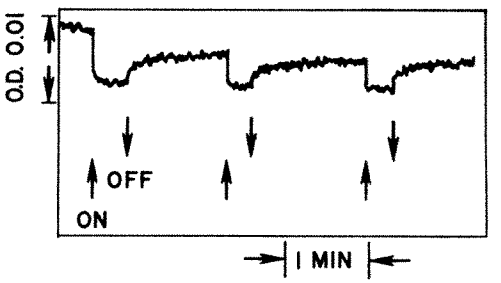

Fig. 1. Kinetics of the photo-induced bleaching at 705 nm in *Anacystis nidulans* at the temperature of liquid nitrogen

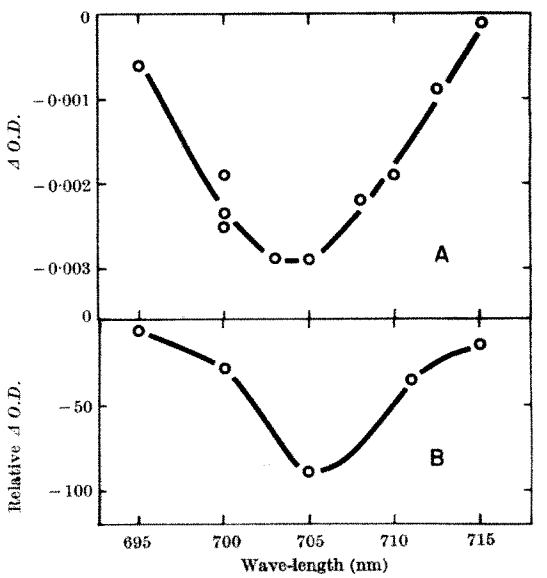

Fig. 2. *A*, Difference spectrum of the reversible photobleaching of *A. nidulans* at the temperature of liquid nitrogen; *B*, difference spectrum of the irreversible component of the photobleaching at liquid nitrogen temperature. This spectrum was obtained by normalizing the irreversible component to the magnitude of the reversible change at 705 nm

blue-green algae, *Anacystis nidulans* and *Plectonema boryanum*. For spinach chloroplasts a much smaller reversible component is observed, yielding a ratio of about 1 : 10. The reversible change is repeatable at liquid nitrogen temperatures for many consecutive measurements with little decrease in magnitude.

The difference absorption spectrum of the reversible component is shown in Fig. 2*A*. In the far red region the difference spectrum obtained closely follows that reported by other investigators[1] for *P*700 at room temperature. An accurate difference spectrum of the irreversible component is more difficult to obtain, since a different sample must be used at each wave-length. The difference spectrum of the irreversible absorption change at the temperature of liquid nitrogen is shown in Fig. 2*B*; this spectrum was obtained by normalizing the irreversible component at each wave-length to the magnitude of the reversible change at 705 nm. The precision of these measurements was less than for the reversible absorption change, but it is clear that the two components of the absorption change have similar spectra in the 705 nm region. Reversible and irreversible components of bleaching are also observed in the Soret region with a peak at 432 nm. The band in this region appears to be smaller than that at 700 nm, both in total amount and in the ratio of reversible to irreversible change.

The partial reversibility of the bleaching of *P*700 at low temperature strengthens an analogy between this pigment and the pigments *P*870 and *P*890 of photosynthetic bacteria. The latter are bleached reversibly by illumination at liquid nitrogen temperature[5].

Effect of Age and Nephrectomy on ε-Lysine Acylase of Rat Kidney

ALTHOUGH a considerable amount of work on physiological changes has been carried out in the remaining kidney after unilateral nephrectomies, surprisingly little work has been reported concerning the change of enzyme levels in the kidney under these conditions. Thus, it was felt worthwhile to undertake an investigation into the effect of age and unilateral nephrectomy on an enzyme, ε-lysine acylase. ε-Lysine acylase was chosen as an illustration, merely because this enzyme has been identified and characterized previously in our laboratory[1].

Sprague–Dawley rats were employed throughout the present experiment and, after unilateral nephrectomy, the animals were fed with 10 per cent glucose solution in tap water. At intervals the animals were killed and the ε-lysine acylase activity was measured. In each case, the enzymatic activity in the nephrectomized kidney on removal served as control. Each kidney was homogenized in 4 volumes of water using a mechanically driven glass homogenizer. The homogenate was incubated with equal volumes of ε-*N*-acetyl-L-lysine solution containing 60 μmoles per ml. After incubation at 38° C in a water bath for 2 h, the reaction was terminated by the addition of 1 N hydrochloric acid to lower the *p*H to about 6·0. After boiling and light centrifugation to remove precipitated protein, the amount of free L-lysine in the supernatant was determined manometrically by lysine decarboxylase. Detailed description of the procedure will be found elsewhere[2]. The protein content of the homogenate was measured by the method of Lowry *et al.*[3]. ε-*N*-Acetyl-L-lysine was prepared according to the method by Neuberger and Sanger[4]. L-Lysine decarboxylase was purchased from Worthington Biochemical Inc. as acetone powder of *Bacterium cadaveris*. The enzymatic activity is expressed as μl. carbon dioxide per h per mg protein (specific activity), and 19·9 μl. carbon dioxide corresponds to 1 μmole of substrate hydrolysed.

As shown in Fig. 1, the specific activity of the enzyme gradually decreased as the age of the animals increased. Age was expressed as the increase in body-weight (the 30 g rats were two weeks old and the 250 g rats two months old). However, the total enzymatic activity increased, owing to the fact that the weight of the kidneys increased in proportion to body-weight as the animals aged. Neither starvation of the animals for up to ten days nor protein-rich diet (30 per cent casein) for three weeks influenced the level of ε-lysine acylase activity, although the high-protein diet has been shown to increase the enzyme of the urea cycle in liver[5].

Fig. 2 illustrates the change in specific activity of ε-lysine acylase in the remaining kidney after unilateral nephrectomy. The numbers in brackets indicate the number of animals used for each point. As seen in Fig. 1, the specific activity of the enzyme reached maxima increase of approximately 35 per cent in three days after the nephrectomy, and thereafter decreased slowly. This observation is similar to the finding of Tomassini[6] of the increase of acid phosphatase in the surviving kidney. Acid phosphatase in all nephrons of the surviving kidney increased sharply until the 5th day after nephrectomy and the decrease began at the 7th–10th day. In the present experiment, the weight of body after operation stayed rather below the value at pre-operation. The increase of the activity of ε-lysine acylase was more dramatic when the total enzymatic activity in the remaining kidney was considered. As also shown in Fig. 2, the total protein increased sharply during the first two days after operation to approximately 40 per cent above the control, and thereafter increased quite slowly, reaching about 47 per cent above the control at the end of the experiment.

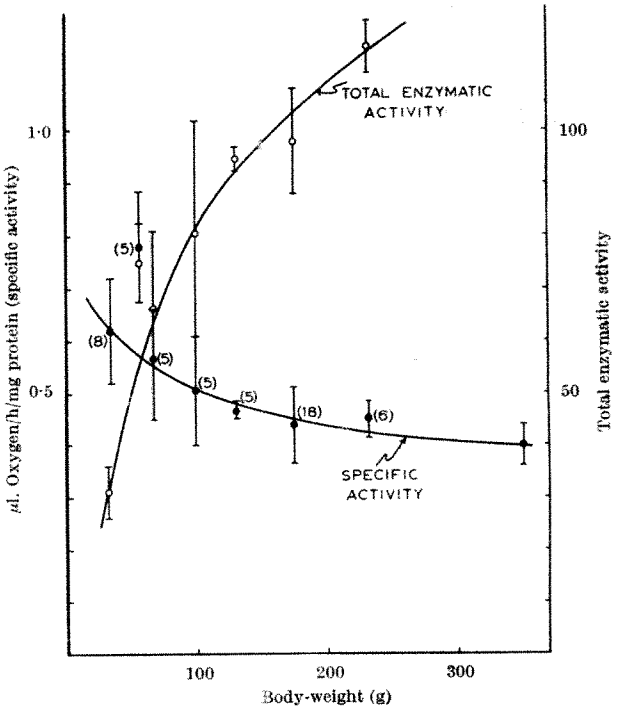

Fig. 1. Relationship between the body-weight, specific activity, and total enzymatic activity of ε-lysine acylase in rat kidney. The numbers in brackets indicate the number of animals used for each point and the body-weight is expressed as the mean value of these animals whose weights were approximately identical

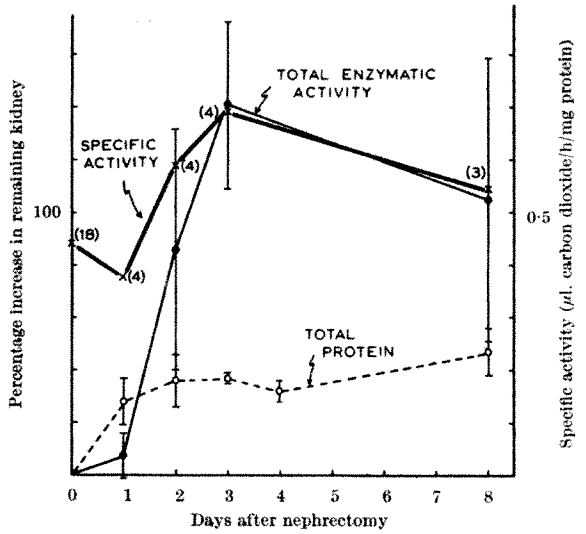

Fig. 2. The effect of unilateral nephrectomy on ε-lysine acylase activity, total enzymatic activity and total protein content in the remaining kidney. The numbers in brackets indicate the number of animals used for each point

On the other hand, the activity of ε-lysine acylase increased to approximately 140 per cent of the level observed in the control in 3 days and remained above 100 per cent even eight days after nephrectomy when the experiment was terminated. The result indicated very clearly that after nephrectomy the activity of ε-lysine acylase in the remaining kidney completely compensated for the loss due to the removal of one kidney, and that this increase in the activity was highly significant because the total protein did not increase as much as the enzyme protein. By the experiments described here, it is impossible to deduce whether there was any preferential *de novo* protein synthesis.

Thus, the present results can be summarized as follows: the specific activity of ε-lysine acylase decreased as the rat grew older, although the total enzymatic activity in the kidney increased considerably. Furthermore, the total enzymatic activity in the remaining kidney after unilateral nephrectomy doubled the amount of the control value in three days while the total protein content increased only approximately 40 per cent during this period, possibly indicating preferential synthesis of this enzyme, and the complete compensation of the function by the remaining kidney as far as the activity of ε-lysine acylase was concerned.

Method of Recording Simultaneously the Positions of Labelled and Unlabelled Compounds on Autoradiographs

A COINCIDENCE technique for paper chromatography has recently been described[1], in which a 'shadowgram' of a chromatogram is produced by placing the chromatogram over a photographic film and exposing the covered film to radiation of a wave-length which is absorbed by the 'spots' on the chromatogram. In this way a 'shadowgram' of purine or pyrimidine 'spots' may be produced by exposing the covered film to an ultra-violet source, or of amino-acid spots (after development with ninhydrin) by exposure to visible light.

In each instance when the film is developed the separated compounds appear as light 'spots' on a dark background and such a 'shadowgram' may be conveniently superimposed on the autoradiograph of its own chromatogram for checking the correspondence of 'spots'.

In this laboratory we have made use of a somewhat similar technique, but one which has the added advantage of providing a record of both labelled and unlabelled compounds on a single film.

In this method an X-ray film is covered with a chromatogram or ionophoresis paper which is clipped firmly in position. The covered film is then illuminated with a suitable source (visible or ultra-violet) for a period sufficient to produce partial exposure of the film except in those areas screened by the 'spots'. The film, with the chromatogram or ionophoresis paper still in place, is then covered and exposure to the radio-active compounds on the paper continued as in the preparation of a normal autoradiograph.

When finally developed the labelled compounds appear as dark 'spots' and the unlabelled compounds as light 'spots' on a grey background, as illustrated in Fig. 1.

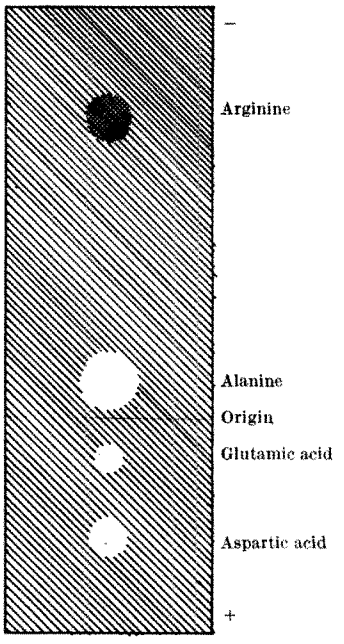

Fig. 1. Diagram showing the position of labelled arginine and unlabelled alanine, glutamic acid and aspartic acid after ionophoresis at *p*H 3·6

Using 'Kodirex' film covered with Whatman 3 *MM* paper, an initial exposure time of 10 min was found suitable for recording the position of amino-acids (developed with ninhydrin) when a Kodak 'Beehive Safelight' fitted with yellow filter ('Wratten' series *OB*), placed 30 cm from the covered film, was used as a light source.

Metabolism of Coumarin by a Micro-organism

RECENT reports described the isolation of a soil organism (*Arthrobacter* sp.) as the source of an enzyme which reduced *o*-coumaric acid to melilotic acid[1-3]. The present communication describes further studies on this enzyme which suggest that it is a flavoprotein and that the flavin moiety is FAD.

The organism was cultured with coumarin as its sole carbon source, and collected as previously described[1,2]. To demonstrate the role of a flavin in the reaction, the enzyme purification described earlier[2] was modified as follows: The enzyme, obtained after ammonium sulphate precipitation, was treated once again with calcium phosphate gel and the mixture clarified by centrifugation at 75,000*g* for 30 min. The supernatant solution was then brought to 50 per cent saturation with solid ammonium sulphate and, after cooling for 30 min, the suspension was centrifuged at 75,000*g* for 30 min. The precipitate was redissolved in a volume of water equal to the original volume of crude extract. This enzyme was dialysed against 4 l. of water changed three times during a 24-h period. This preparation was used in all the experiments reported here.

Attempts to separate the flavin from the protein using ammonium sulphate precipitation followed by treatment with acid, as described by Strittmatter[4], were unsuccessful in that the enzyme was irreversibly inactivated. It was found that the above modification of the original purification procedure[2] separated the flavin from the apoenzyme with only minimal loss of enzyme activity.

Table 1 shows the effects of the addition of various flavins on NADH : *o*-coumarate oxidoreductase. It can be seen that FAD at $6{\cdot}6 \times 10^{-5}$ M doubled the activity of the enzyme. The other flavins were virtually without effect. When FAD was added after the addition of inhibiting concentrations of partial structural analogues of FAD or various anions (Table 2), activity was in most cases restored to greater than control levels. Other flavins such as FMN and riboflavin either had no effect, or inhibited enzyme activity. It appears, therefore, that FAD is a specific co-factor for NADH : *o*-coumarate oxidoreductase.

The reduced form of FAD ($FADH_2$) bound to the enzyme surface may function as the direct electron donor in the reduction of *o*-coumaric acid to melilotic acid.

It has been shown that the enzyme, D-amino-acid oxidase, a flavoprotein isolated from pig kidneys[5,6], was inhibited by various anions, as well as by partial structural analogues of FAD. In both cases, FAD added to the reaction mixture restored the lost activity[5,6]. The interpretation of these data was that FMN and the structural analogues exerted their inhibition by competing with FAD for binding sites on the protein. The inhibition by anions was alleged to represent competition with dissociated phosphoryl groups in FAD. The results of studies with NADH : *o*-coumarate oxidoreductase suggest that it is similar to D-amino-acid oxidase with respect to the manner in which the FAD is bound to the apoenzyme.

o-Coumaric acid and dihydrocoumarin were purchased from K and K Laboratories, Inc. Melilotic acid was prepared as described previously[2]. NADH was purchased from Pabst Laboratories, Inc. FAD, FMN, riboflavin, adenine, adenosine, adenylic acid, ADP and ATP were obtained from Mann Laboratories, Inc. Coumarin was bought from Eastman Organic Chemicals.

Table 1. EFFECT OF VARIOUS FLAVIN COMPOUNDS ON NADH : *o*-COUMARATE OXIDOREDUCTASE ACTIVITY

Co-factor added	Final concentration	mμ Moles NADH oxidized/minute
Control	—	100
FAD	$6{\cdot}6 \times 10^{-5}$ M	200
FAD	$1{\cdot}3 \times 10^{-4}$ M	116
FMN	$6{\cdot}6 \times 10^{-5}$ M	100
Riboflavin	$6{\cdot}6 \times 10^{-5}$ M	87

The basic reaction mixture contained in a total volume of 3 ml. consisted of the following: 440 mμmoles of *o*-coumaric acid; 300 mμmoles of NADH; 0·1 ml. of enzyme, and 4·8 mμmoles phosphate buffer, *p*H 7·3. When a flavin was included in the reaction mixture, there was a proportionate reduction in the volume of buffer added. Enzymatic activity was assayed spectrophotometrically by recording the decrease in absorbancy of NADH at 340 mμ over a 60-sec interval.

Table 2. (*A*) EFFECT OF ANIONS AND PARTIAL STRUCTURAL ANALOGUES OF FAD ON NADH : *o*-COUMARATE OXIDOREDUCTASE ACTIVITY

PHYSIOLOGY

Extracellular Recording of Converging Input on Cortical Neurones using a Flexible Microelectrode

THE convergence of different modalities of sensory input on restricted areas of the cerebral cortex has received much experimental attention in recent years[1-5]. Such investigations are valuable for an understanding of the integrative capacities of the cerebral cortex.

One cortical association area studied in detail at the cellular level[4,5] showed differential responsiveness to various peripheral and central stimulations. Intracellular recordings indicated that excitatory and inhibitory postsynaptic potentials would, for many cells, determine the responsiveness of a cell, or the lack thereof, to converging input. Other convergences occurred before the level of the impaled cortical cell.

It seems likely, because of strong convergence of input, that non-primary, association areas may demonstrate especially good integrative capacities. Furthermore, a cell which is unequally responsive to different modalities of sensory stimulation may be able to alter its pattern or extent of responsiveness under different conditions. It will be necessary ultimately to consider the likelihood of a differentially responsive cortical cell changing its discharge characteristics during certain behavioural situations.

More descriptive information about convergence on neurones in association cortex is needed, and before long-term investigation of neuronal activity is possible, means must be developed of recording unit discharges for days and weeks. Previous microelectrode studies of extracellular cortical activity have been successful for minutes or several hours and these experiments have yielded valuable information about unit discharges to sensory stimulation under several conditions in the unanaesthetized mammal[6–8].

In the present investigations, carried out on twenty-four cats anaesthetized with chloralose (55 mg/kg initially), a simple microelectrode was used for stable recording from neurones in an association area of the cerebral cortex (anterior marginal gyrus). Extracellular recordings could be routinely obtained for many hours with the flexible electrode and thus high reliability of neuronal discharges to the converging inputs could be established.

Microelectrodes were made from 80-μ nichrome wire, electrolytically sharpened to a tip of less than 5μ, with a taper of about 300μ, and insulated with lacquer to within about 25μ of the tip. The experimental procedure consisted of inserting the flexible microelectrode through a small opening in the skull and through the slit meninges at an angle which permitted electrode movement through the cortex approximately horizontal to the cortical surface and roughly parallel with the cortical cell layers (Fig. 1). With the flexible electrode inserted several millimetres, no provision for controlling brain movement was necessary in most cases. The electrode, held in the microdrive about 2 cm from the tip, had sufficient flexibility to allow it to move with brain pulsations without being dislodged from the vicinity of an active cell.

Extracellular recordings from well-isolated cells could be made for exceedingly long periods. Figs. 2 and 3 are from a cell which was studied for nearly 4 h with little change in spike configuration. In one cat, with electrodes sealed at the opening in the skull with dental acrylic, single-cell discharges were observed for 30 h, before the experiment was deliberately terminated.

Data were collected on eighty-one cells in the anterior marginal gyrus at an average location of A 20·5 (ref. 9) and with the entrance made at about A 15. Recordings and stimulations were used as previously described[3,4]. As the microelectrode was advanced, animals were simultaneously stimulated with a photic flash (P, 5 msec), an auditory click (A, 0·01 msec), and contralateral forepaw shock (CFP, 0·01 msec) every 2 sec. Nearly all cells selected for study were fired by the combined stimuli. Hubel's criteria[10] for distinguishing between cell and fibre spikes were used. Because one purpose of the investigation was to determine the reliability of unit recordings using the flexible microelectrode, no analysis of convergence was attempted until the cellular activity had been observed for at least 15–20 min without any sign of injury. Nearly all cells were investigated for at least 45 min, many for several hours.

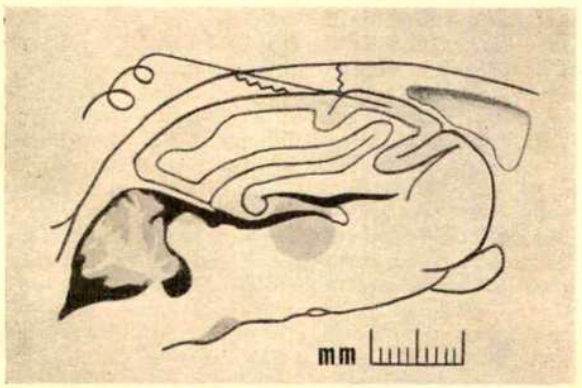

Fig. 1. Drawing of longitudinal section of cat brain and skull about 3 mm from midline. Flexible microelectrode seen in the angle approach to cortex of the anterior marginal gyrus

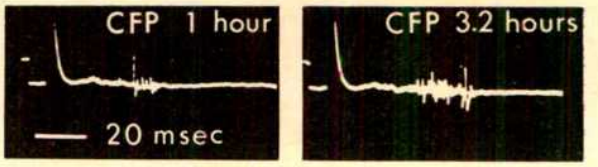

Fig. 2. Extracellular recording from a cortical neurone firing to contralateral forepaw shock 1 h and 3·2 h after its initial isolation. Latency remained constant at about 35 msec. Later recording shows spikes from another cell which appeared as depth of anaesthesia decreased. Foot shock intensity just below that which produced motor twitch. CFP probability 40 min after finding the cell was 0·52, at 3 h it was 0·74. Bar at first break in baseline in 200 μV. Second break is point of CFP shock. Downward deflexion positive here and in Fig. 3

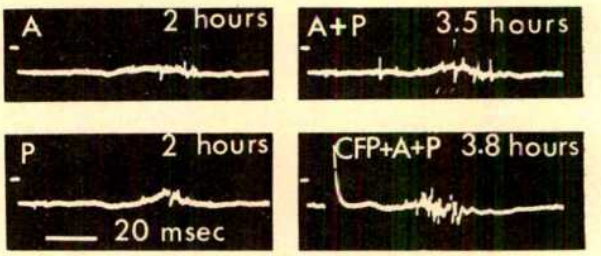

Fig. 3. Convergence of input on the same cell as in Fig. 2. Cell discharged to auditory and photic stimulation at 2 h with latencies of 49 and 53 msec and probabilities at 1·8 h of 0·48 and 0·48. Pairing A and P at 3·5 h produced other cellular spikes and slightly increased the probability of firing by the principal cell to 0·54. All three stimuli together at 3·8 h resulted in multiple spikes and further summation for a probability of 0·98. Calibration as in Fig. 2. A and P artefacts occur as downward deflexions in baseline

Rates of cellular discharge, as observed previously under chloralose, were low. Only sixty-four of the eighty-one cells were spontaneously active; nine of these could not be fired by any of the three inputs. Average spontaneous frequency of the fifty-five cells was slightly less than 2 sec.

Of the eighty-one cells, eight were exclusively monosensory, 2 P, 2 A, and 4 CFP. Fifteen were bisensory, that is, they responded to each of two inputs. Since the study of convergence of all three inputs on a particular cell was intended, attention is directed to the forty-nine cells which fired to each of the three inputs. Table 1 shows that cells in the anterior marginal gyrus had low probabilities of firing, much lower than did those in the anterior middle suprasylvian gyrus[3,4].

Table 1. AVERAGED PROBABILITIES OF FIRING (p) AND LATENCIES IN MSEC (lat) FOR FORTY-NINE CELLS FIRING TO ALL THREE INPUTS. CELLS CLASSIFIED AS PREFERENTIALLY RESPONSIVE OR EQUALLY RESPONSIVE (ER)

	P		A		CFP		
Class	p	lat	p	lat	p	lat	Signif.
11 P	0·67	61 (8)*	0·38	48 (7)	0·30	47 (6)	$\ll$0·001†
8 A	0·32	93 (4)	0·74	41 (6)	0·33	53 (4)	$<$0·001†
5 CFP	0·36	74 (3)	0·32	43 (4)	0·60	29 (4)	0·02†
25 (ER)	0·52	73 (18)	0·51	46 (18)	0·52	36 (16)	$\ll$0·001‡

* Number of latency measurements in parentheses.
† Significance level for six t ratios of mean p differences, for example, 11 P cells compared with A and CFP inputs.
‡ Significance level for three t ratios of latency differences for the twenty-five equally responsive cells. Numbers too small for latency difference tests on the other cells.

Twenty-four cells were classified as preferentially responsive on the basis of highest firing probability. As indicated in Table 1 these cells had a significantly higher probability of firing to a single input than to either of the other two. (It is worth emphasizing, as noted before[3,4], that chloralose in light to medium concentrations does not produce equal responsiveness of all cortical neurones to all peripheral stimuli.) Preferential responsiveness was not directly reflected in latency differences. For the twenty-five equally responsive cells though, latencies were significantly different with the order from shortest to longest,

being CFP, A, P. There were also differences in latencies between the two general categories. Table 1 shows that latencies of cells in a preferentially responsive class were in all three instances less than latencies of equally responsive cells firing to the same modality of stimulation.

These data are all consistent with the interpretation that an important portion of a given population of cells in association cortex can be expected to demonstrate differential responsiveness to converging sensory input. Another portion would show equal convergence. This fact is supported by the results given in Table 1 and also by instances of occlusive interactions observed when firing probabilities were sufficiently high for such tests to be made.

Simultaneous pairing of two stimuli yielded unequivocal data on cellular integrative mechanisms. Sixty cells were tested with pairings of supra- and/or sub-threshold stimuli. Fifteen cells showed summation of input, seven facilitation (one stimulus of the pair not producing any cell discharge alone), and five inhibition. Summation, as illustrated in Fig. 3, could be seen in some cells only with pairing of all three inputs. With the cell illustrated a distinct latency decrease occurred, plus the appearance of additional cell spikes.

These results show that with a simple flexible microelectrode reliable extracellular recordings can be obtained from cortical neurones for at least many hours. The data also indicate that the anterior marginal gyrus of the cat contains neurones unequally responsive to different modalities of sensory input and it has cellular discharge characteristics reflecting summation, facilitation and inhibition.

Inhibition of β-D-Glucosiduronic Acid Conjugation by Eugenol

IT has been claimed that eugenol, 4-oxy-3-methoxy-1-allylbenzoic acid, has mucinogenic activity and that it has a beneficial effect on gastric ulcers[1,2]. The gastric wall contains various uronic acid containing mucopolysaccharides, the formation of which is possibly dependent on a proper coupling capacity of β-D-glucosiduronic acid (UDPGA). Evidence has been obtained which indicates that the amount and type of mucopolysaccharides in tissues probably have some bearing on the mechanism of ulcer formation[3]. This investigation was undertaken in order to determine whether eugenol has any effect on the glucuronation of an exogenic substance. The effect on the whole conjugation capacity of the tissue, as well as on the UDPGA transferase enzyme, was also considered in the investigation.

Wistar rats and guinea-pigs were used as test subjects. The whole conjugation was followed using a modification of the method developed by Levvy and Storey[5,6]. The UDPGA transferase activity was determined by the method of Bogell and Leloir[7]. This method requires washed microsomes, UDPGA (Sigma) and *p*-nitrophenol. Eugenol was dissolved in 0·2 per cent 'Triton *X*-100' solution. The oxygen consumption was measured in a Warburg apparatus.

The effect of eugenol on the formation of *o*-aminophenol glucuronide by liver slices is shown in Fig. 1. It can be seen that a 50 per cent inhibition is obtained with a eugenol concentration of 2 μg/ml. in the incubation solution. The same result was obtained using 50 and 100 μg aminophenol. At a concentration of 200 μg/ml. or above, eugenol constantly caused an activity less than 5 per cent of that of the controls; 250 μg resulted in some cloudiness. At a concentration of 100 μg/ml. the oxygen consumption was identical to that of both the controls and also to the controls without the tissue specimens.

Several additional experiments were carried out in order to elucidate the nature of the inhibitory effect of eugenol. When eugenol (100 μg) was added after the tissue had been incubated for 1 h, a 70 per cent reduction in glucuronide synthesis was produced as compared with the control.

Eugenol, when added just before deproteinization and at subsequent stages, had no effect. This eliminates the possibility of there having been any interference in the analytical procedure.

In the *in vivo* experiments, 3 ml. of 5 per cent eugenol was given to the animals and this virtually resulted in a complete inhibition in rinsed stomach, and about a 75 per cent inhibition in duodenal slices. The results with liver were just above normal. No effect could be detected after 24 h, but it was still complete 6 h after the eugenol had been administered; the effect was variable after 12 h. Histological studies of the stomach revealed desquamation of the surface epithelium and punctate haemorrhages in the pylorus and glandular stomach. Cellular exudate was present on the surface; this was visible to the naked eye. No attempt was made to find the least effective dose *in vivo*. When tissue slices were placed in a solution of 0·025 per cent eugenol in Ringer's solution for 2 min before they were rinsed and transferred to the Warburg vessel, the synthesis dropped to less than 25 per cent of the controls. The effect was the same for stomach, duodenum and liver. No attempt was made,

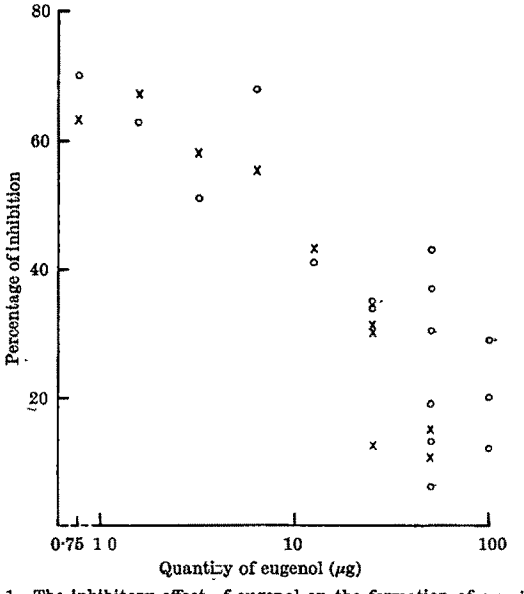

Fig. 1. The inhibitory effect of eugenol on the formation of *o*-aminophenolglucuronide by liver slices

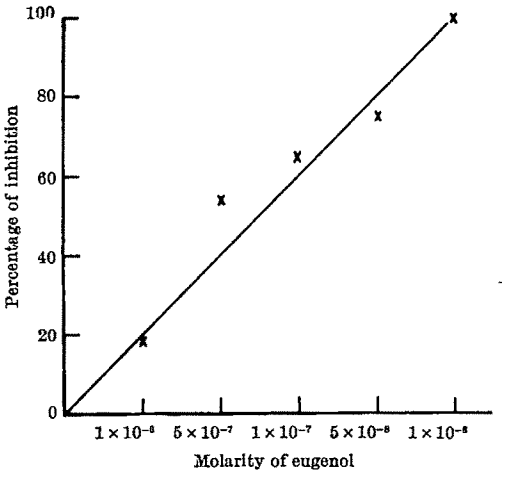

Fig. 2. The inhibitory effect of eugenol on the glucuronyl transferase activity of the liver

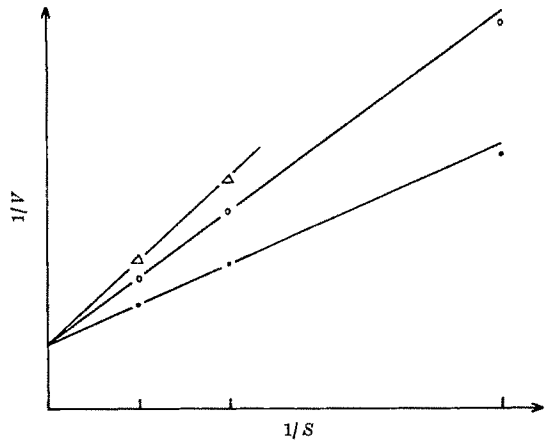

Fig. 3. The nature of the glucuronide conjugation inhibition by eugenol according to Lineweaver-Burk. △, 2.5×10^{-7} M eugenol, ○, 1×10^{-7} M eugenol; ●, control

however, to find the shortest effective time and lowest effective concentration.

When the specific effect of eugenol on the enzyme in the last stage of the conjugation reaction system (that is, on the glucuronyl transferase) was studied, it was found that for this enzyme the inhibition is K_{50} 2.5×10^{-7}. The correlation between the degree of inhibition and the concentration of eugenol is shown in Fig. 2. The nature of this inhibition has been studied by preparing a Lineweaver-Burk plot of the results as shown in Fig. 3. It can be considered that the inhibition is of a competitive nature. The concentration of *p*-nitrophenol was also varied, but with the methods used no satisfactory results were obtained. The 'Triton *X*-100' was used in the experiments in order to increase the solubility of eugenol. It had no inhibitory effect at a concentration of 0·2 per cent. However, if the concentration was increased to more than 1 per cent, a very small inhibitory effect was obtained.

It has been possible to demonstrate the inhibition of β-D-glucosiduronic acid conjugation with eugenol. An important point in the reaction system is that UDPGA transferase would seem to be inhibited. It could be that this is not the only enzyme in the glucuronic acid conjugation system the activity of which is inhibited.

These results are in agreement with our earlier observations that eugenol can lower the quantity of salicylamide glucuronide formed in dogs when it is fed to them together with salicylamide[8]. It is difficult at present to correlate these observations with the mucinogenic effect of eugenol demonstrated by Hollander *et al.*

Presynaptic Inhibition in Primate Lateral Geniculate Nucleus

SINCE their discovery[1-4], the effects of midbrain stimulation on excitability of the visual system have been studied extensively. Work on the squirrel monkey[5,6] has shown that the centrencephalic system exerts a powerful control over transmission through the lateral geniculate nucleus (LGN) for both photically and electrically elicited responses. Initial experiments showed facilitation following electrical stimulation of the mesencephalic reticular formation or natural alerting stimuli. Recent experiments, however, have shown that a brief period of inhibition precedes the facilitation and, as set forth below, strongly suggest that this inhibition is presynaptic in nature.

The phenomenon of presynaptic inhibition has been thoroughly reviewed by Eccles[7]. Among the characteristics which, in the mammalian central nervous system, reliably distinguish presynaptic from postsynaptic inhibition are susceptibility to different pharmacological agents. Strychnine, for instance, blocks most types of postsynaptic inhibition without affecting presynaptic inhibition, whereas picrotoxin strongly depresses the latter while leaving postsynaptic inhibition intact.

In the present investigation, 32 squirrel monkeys (*Saimiri sciureus*) were lightly anaesthetized; 20 with 'Diabutal' (sodium pentobarbital), 25 mg/kg, and 12 with 'Dial', 0·3 ml./kg. Pairs of electrodes made from 0·25 mm diameter 'Nichrome' wire were introduced into the optic tract (stereotaxic co-ordinates [8] : *A*9, *L*5, −1), optic radiation (*A*1, *L*10, +3), mesencephalic reticular

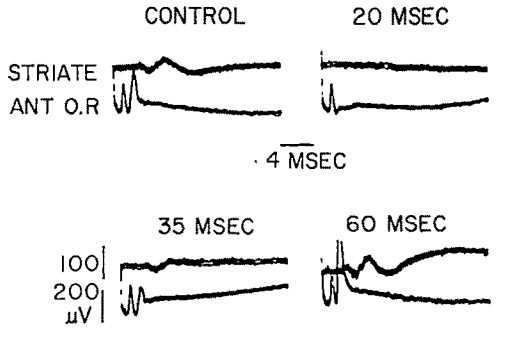

Fig. 1. Squirrel monkey *R*291. Control level of response in anterior optic radiation (Ant. O.R.) and striate cortex to stimulation of optic tract (10 V, 0·03 msec), bipolar electrodes. First peak in Ant. O.R., presynaptic or optic tract component; second peak, postsynaptic response conducted from LGN. Application of single pulse (15 V, 0·1 msec) to mesencephalic reticular formation 20 msec prior to optic tract stimulation abolishes responses in radiation and cortex. At 35-msec interval, inhibition not complete. Note at 60 msec, three-fold enhancement of postsynaptic responses. Presynaptic component unchanged throughout

formation (*A2, L2,* +2 to ±0), and posterior area striata. All electrode sites were confirmed histologically.

From the specified position in the optic radiation, both pre- and post-synaptic components[5,9] for the response of the LGN can be seen following an electrical pulse applied to the optic tract (Fig. 1). In 23 of the 32 monkeys, application of a single pulse (10 V, 0·1 msec) to the midbrain site prior to stimulation of the optic tract produced the sequence of inhibition and facilitation seen in Figs. 1, 2 and 3. The inhibition was always earlier than the facilitation. Facilitatory effects alone were found in six animals, and inhibition alone in three. The inhibition had a latency of 5–8 msec, was maximal at 20–30 msec (completely abolishing responses in some preparations), and then usually passed gradually into facilitation at about 40–80 msec. Two spikes representing contributions from magno- and parvo-cellular components of the LGN can often be recorded from the radiation following stimulation of the optic tract. Both spikes appeared equally influenced by mesencephalic stimulation. Responses in area striata varied roughly *pari passu* with those in the radiation, although adequate analysis of cortical excitability *per se* has not yet been made. Bilateral enucleation (Fig. 2) or removal of most of area striata did not change these effects beyond altering the background against which they occurred[10].

In twelve of the monkeys in which inhibition was found, strychnine sulphate or picrotoxin were given in progressive doses, up to convulsive levels. Strychnine (up to 0·4 mg/kg) did not alter the inhibitory effects in any of the monkeys used, whereas picrotoxin (1·0–1·5 mg/kg) consistently abolished all the inhibitory effects in each of the nine monkeys tested. The effects of picrotoxin subsided after about 2 h, at which time inhibitory effects returned (Fig. 3). The lack of effect of strychnine could then be demonstrated in the same preparation. Injection of additional pentobarbital prolonged and augmented the inhibitory effect (Fig. 2) and could cut short the action of picrotoxin. Intravenous injection of mephenesin (80 mg/kg) in one animal also abolished the inhibition.

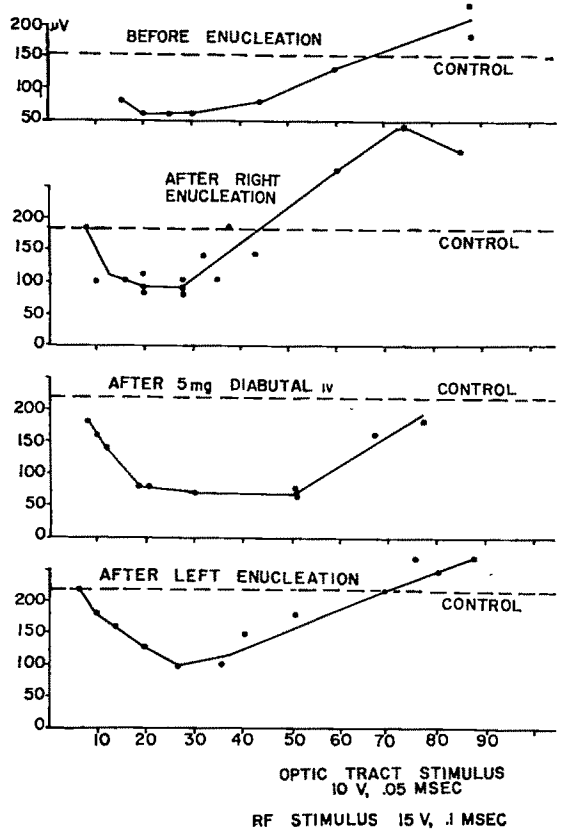

Fig. 2. Amplitude of response in optic radiation under various conditions. Ordinate, response amplitude in μV; abscissa, interval by which mesencephalic precedes optic tract stimulus. Solid line, postsynaptic response in optic radiation at varying intervals following mesencephalic stimulation; dotted line, control levels. Note degree of inhibition unchanged by removal of both eyes although control level of excitability shifts. Additional dose of sodium pentobarbital lengthens and potentiates the inhibition

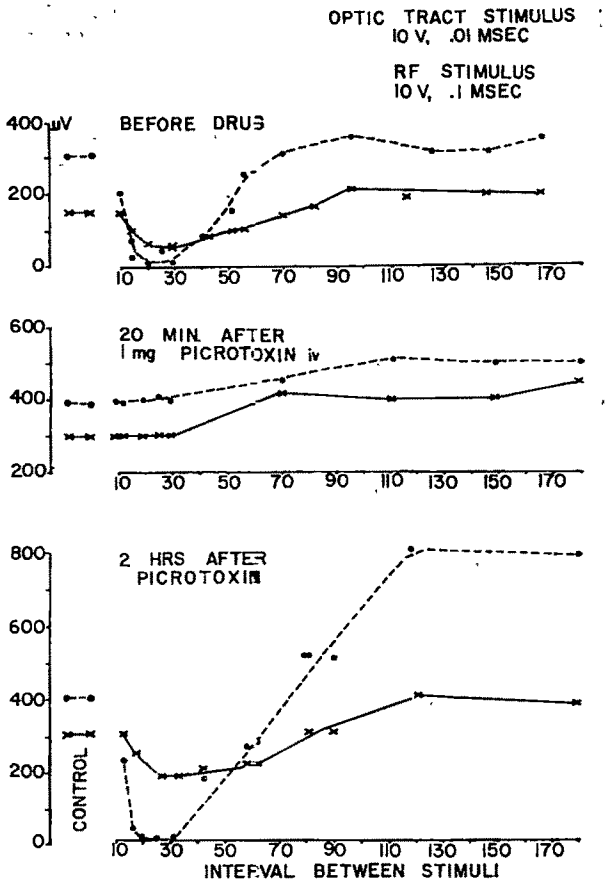

Fig. 3. Excitability curves of responses in optic radiation and striate cortex before and after intravenous picrotoxin (1·5 mg/kg). Ordinate and abscissa as in Fig. 2. Solid line, postsynaptic response in optic radiation at varying intervals dotted line, cortical response (peak to peak). At left, control responses to optic tract stimulus (without mesencephalic stimulus). Note abolition of inhibition 20 min after picrotoxin administration, and recovery after 2 h. Increased responsivity of cortex in latter is partly from diminishing barbiturate anaesthesia

The pharmacological effects on this inhibition in the LGN are thus identical with those seen for presynaptic inhibition in the spinal cord[7,11], and the latency and time course are similar at the two sites. The inhibition endures for a shorter time in the LGN, but this is probably because it is overwhelmed by later-developing facilitation. Slow potential changes which might correspond with those recorded from dorsal roots or cord dorsum in association with presynaptic inhibition can be registered in the optic radiation and optic tract, but the probability of mixed facilitatory and inhibitory effects makes their interpretation difficult at this time. Morphologically, axo-axonic endings which could function in presynaptic inhibition have been described in the spinal cord[12] and there are preliminary reports[13,14] that such endings are also abundant in the LGN of cats Axo-axonal endings have been described for the LGN of macaques[15], although the apparent functional relations here are difficult to interpret. In any event, the electrophysiological and pharmacological evidence is all concordant with the possibility that the inhibition exerted by the centrencephalic system on transmission in the LGN is presynaptic in nature.

This research was supported by the National Institute of Neurological Diseases and Blindness, National Insti-

utes of Health. Paul D. Wilson held a Public Health Service fellowship from the National Institute of Mental Health, National Institutes of Health.

Note added in proof. We have found that potentials antidromically elicited in the optic tract by submaximal stimulation of LGN increase 10–20 per cent during the period of inhibition. Such manifestation of increased excitability in presynaptic terminals is exactly concordant with expectations for presynaptic inhibition[7].

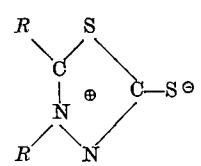
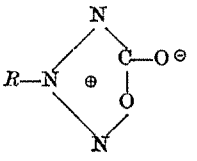
PHARMACOLOGY



A New Class of Hypotensive Agents

FOR several years we have been engaged at these laboratories in an investigation of the physical, chemical, and pharmacological properties of various mesoionic heterocyclic ring systems. In the first of these systems investigated—the sydnones (I)—we found marked central nervous system stimulation[1–6].



(I)

More recently, we have investigated a series of sulphur-containing mesoionic heterocyclic compounds with a ring isoelectronic with the sydnones. These compounds—the mesoionic 1,3,4-thiadiazoles (II)—were found to have antimicrobial activity[7,8].

(II)

Our continuing interest in the potential pharmacological activity of the mesoionic compounds, as well as the possibility of structure-activity correlations, led us to synthesize and study a number of mesoionic compounds known as the ψ-oxatriazoles (III). This class of heterocyclic compounds had been known since 1933[9], although the structure and nomenclature at present accepted were not established until more recently[10,11]. Later investigations have yielded additional methods of synthesis[12,13].

(III)

Several of these compounds have been synthesized by means of the procedure previously described[10] with minor modifications. The compounds made and tested were the isopropyl, the secondary butyl, the 3-pentyl, the *cyclo*hexyl, the 1,3 dimethyl butyl and the 1,2,2-trimethyl propyl derivatives of the basic structure. They all produced a hypotensive effect when injected intravenously into anaesthetized dogs, in a dose of 5 mg/kg as a 1 per cent solution in a 1 : 1 mixture of polyethylene glycol and normal saline. The fall in blood pressure ranged from about 6 per cent with the 1,3-dimethyl butyl compound, to 30 per cent with the *cyclo*hexyl compound, and the duration of action ranged from 1 to 2 h. The polyethylene glycol vehicle by itself was found not to affect blood pressure. Pretreatment with the antihistamine pyribenzamine did not prevent the depressor effects of the compounds, so that release of histamine is considered to be an unlikely mechanism of action. Pretreatment with the compounds appeared to potentiate responses to epinephrine and to decrease responses to norepinephrine. It is possible that some of the hypotensive effects are due to competition with norepinephrine for adrenergic receptors.

This preliminary investigation indicates that the pseudo-oxatriazoles as a group possess interesting hypotensive effects. We are now in the process of investigating these properties more intensively.

Antagonism of Digitalis Arrhythmia by Pronethalol : a Neural Phenomenon?

THE depression by pronethalol of ventricular arrhythmia induced by digitalis, and of ventricular escape during vagal stimulation, is apparently not related to the capacity of this drug to block the cardiac effects of exogenous catecholamines[1–3]. Roberts *et al.*[3] pointed out

that the actions of pronethalol on the digitalis-induced arrhythmia and on vagal escape closely resemble those of reserpine and β-TM10—agents which act on sympathetic nerve terminals—and suggested that pronethalol may also affect the activity of sympathetic post-ganglionic nerve terminals.

To determine whether pronethalol acts on nerve terminals, we have examined the effects of the drug on cat soleus motor nerve terminals. Soleus axons normally respond to a single stimulus with a single action potential, but after a period of high-frequency stimulation the response to a single stimulus is repetitive. The post-tetanic repetitive activity (PTR) which is generated in the motor nerve terminal[4] is highly sensitive to neurotropic drugs[5–7]. Furthermore, the repetitive activity is transmitted to the soleus muscle where it causes an increase in isometric contraction strength (post-tetanic potentiation (PTP))[8]. Because of this direct link between PTR and PTP, soleus muscle PTP provides a simple method for assessing drug action on nerve terminals. The pharmacological similarity of motor and sympathetic nerve terminals is indicated in a recent report[9] which states that *d*-tubocurarine, dihydro-β-erythroidine and decamethonium block sympathetic post-ganglionic activity; these drugs profoundly depress the motor nerve terminal[10,11]. Conversely, Burn and Seltzer[9] found that bretyllium and guanethidine exert a blocking action in the rat phrenic-nerve–diaphragm preparation.

The details of our methods have been published[4,8]. In brief, cats were anaesthetized with 80 mg α-chloralose/kg and the popliteal fossa dissected to expose the soleus muscle and its nerve and blood supplies. The leg was mounted in a modified Brown–Shuster myograph and the soleus tendon attached to an isometric electrical strain gauge. The neural origin of the drug effects on PTP was confirmed, in several experiments, by monitoring effects on PTR in the ventral roots of soleus axons. Supramaximal rectangular stimuli, 0·1 msec in duration, were applied to the soleus nerve at a rate of 0·4 c/s. A high-frequency stimulus—10 sec at 400 c/s—was interposed every 5 min. Crystalline pronethalol (Ayerst) was dissolved in 0·85 per cent sodium chloride solution. The volume of injection was standardized at 0·1 ml./kg intra-arterially and 0·5 ml./kg intravenously, and the concentration of the pronethalol solutions adjusted accordingly.

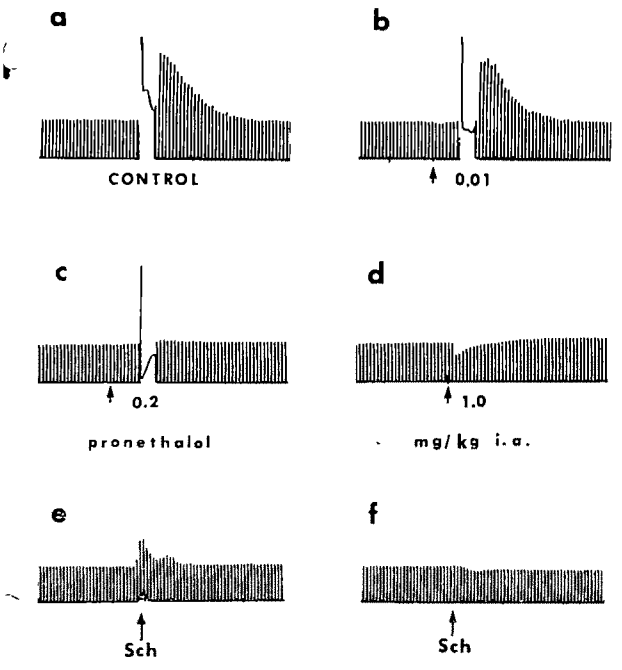

Fig. 1 Pronethalol depression of PTP (*a*, *b*, *c*) and neuromuscular block (*d*). *e* and *f*, from another experiment, show the effects of 0·2 μg succinylcholine/kg intra-arterially before and 80 min after 5 mg pronethalol/kg intravenously

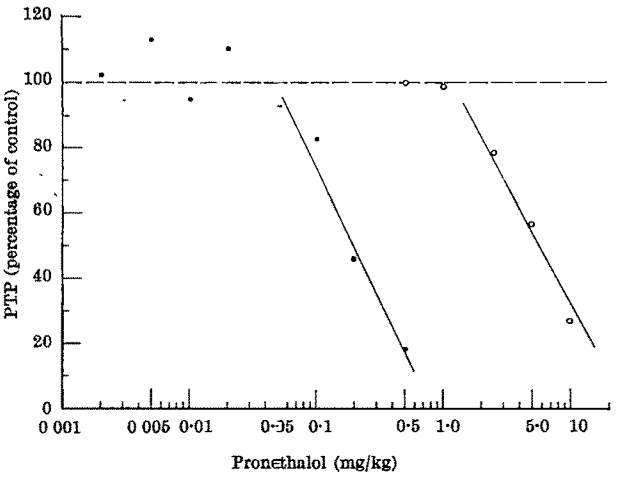

Fig. 2. Dose-response relationships between pronethalol and PTP. ●, Intra-arterial; ○, intravenous

The principal effects of pronethalol, illustrated in Fig. 1, are reduction of PTP and—with higher doses—blockade of neuromuscular transmission. The former results from a pronethalol action on the motor nerve terminal; recordings from ventral root axons confirm that pronethalol reduces PTP by attenuating PTR. The neuromuscular blockade is seldom produced by sub-lethal intravenous doses of pronethalol, but is readily produced by intra-arterial injections. It is presumably caused by depression of the motor nerve terminal as, on a dose scale, it follows directly on the abolition of PTP. The blockade is increased by edrophonium.

The dose–response relationships between pronethalol and PTP suppression are shown in Fig. 2. The results with intravenous administration are of particular interest because they indicate that depression of neural activity occurs with pronethalol doses which afford protection against the ventricular arrhythmia induced by digitalis[1–3]. It is of further interest that pronethalol is about three times as potent in suppressing PTP as diphenylhydantoin[5,12]—another neurotropic drug which has been observed to suppress digitalis arrhythmias[13].

The maximum pronethalol effect on PTP occurs within 2 min, and its duration is a function of dose. Apparently, complete recovery from the intravenous administration of 2·5, 5 and 10 mg/kg occurs in about 25 min, 35 min and 60 min, respectively. Re-administration of the drug at the time of apparent recovery, however, results in a greater effect than that of the initial injection—an indication of continued presence of sub-threshold concentrations of drug.

An additional pronethalol effect on PTP is indicated in Fig. 2. Small, rapidly administered intra-arterial doses produce a transient increase in PTP in roughly two-thirds of the experiments. The effect does not seem to occur with intravenously administered drug. Given by the latter method, however, the drug occasionally produces a small (about 10 per cent) increase in the muscle response to single stimuli. This effect, which has a latency of about 30 min and a duration of several hours, is not accompanied by muscle or nerve repetitive activity and apparently results from a drug effect on the muscle. (For possible mechanisms, see ref. 14.)

Pronethalol also suppresses drug-induced neural repetitive activity. Drugs such as physostigmine, 3-hydroxyphenyltriethylammonium ion (3-OHPTEA) and succinylcholine effect repetitive activity in the motor nerve terminal and potentiation of soleus muscle contraction strength[15,16]. The enhanced muscle activity, like

PTP, is caused by the neural repetitive activity, and consequently its suppression, like that of PTP, indicates a drug effect on the motor nerve terminal. Fig. 1 shows the effects of 0·2 μg succinylcholine/kg before and 80 min after the intravenous administration of 5 mg pronethalol/kg. The effects of physostigmine and 3-OHPTEA are similarly but less strongly reduced.

There is abundant evidence of pronethalol action on other neural systems. Convulsions are one of the principal toxic effects of the drug[17,18]. Recently, Vaughan Williams *et al.*[18,19] have described a variety of spinal reflexes which are affected by pronethalol. These effects, which are probably best interpreted on the basis of pronethalol depression of intra-medullary nerve terminal activity, occur with the same range of doses producing antagonism of the digitalis-induced arrhythmia.

Other drugs, such as β-TM10 and procaine, which depress digitalis arrhythmias, also affect nerve terminals[20,21]. The accumulated evidence therefore indicates that drugs which depress the digitalis-induced ventricular arrhythmia also depress nerve terminal activity. This correlation suggests that some of the digitalis arrhythmias and their antagonism by pronethalol and other drugs may be neural phenomena.

We are indebted to the U.S. Public Health Service for its support and to Mr. Dalton Chiscolm for technical assistance.

A New Drug for the Treatment of Fascioliasis in Sheep and Cattle

ALTHOUGH a number of drugs are available for the treatment of liver fluke disease in sheep and cattle, they are all liable to produce unpredictable toxic effects, with occasional deaths, when used under farm conditions. This is particularly true in cattle, and the precautionary measures often required during their use are such that valuable animals may not be treated routinely for the condition. These untreated animals act as important reservoir hosts for the parasite and thus help perpetuate the disease.

The problem has led us to conduct a search for a safe and reliable treatment for fascioliasis, and we now report the discovery of a compound which appears to satisfy this need. This compound (I) is 2,2′-dihydroxy-3,3′,5,5′,6-pentachlorobenzanilide (U.K. patent applications Nos. 32129/63 and 32130/63), which is a white crystalline solid melting at 208° C, virtually insoluble in water but moderately soluble in the common organic solvents.

(I)

The activity of this compound was first demonstrated in a series of tests against adult and immature *Fasciola hepatica* infections produced experimentally in rats and mice. The definition of liver fluke maturity which we feel important in relation to the disease process, and which we have therefore adopted in describing drug activity, refers to the actual location of the parasite in the liver and not to the onset of egg production. Thus our test against 'mature' liver flukes refers to all flukes present in the bile duct of rats 12 weeks after an experimental infection, irrespective of whether these parasites are producing eggs or not. Our 'immature' test is carried out against 3-week-old *F. hepatica* infections in mice because the parasites are still migrating through the liver tissue at this time.

The results achieved with 2,2′-dihydroxy-3,3′,5,5′,6-pentachlorobenzanilide in this test system are compared in Table 1 with those of other drugs, known to be effective against liver flukes.

It can be seen that 2,2′-dihydroxy-3,3′,5,5′,6-pentachlorobenzanilide is highly effective against adult flukes in the rat and has a therapeutic safety margin which exceeds that of the other drugs. However, like the other drugs, its action against 'immature' flukes in mice is relatively poor, and consequently near-toxic levels of compound have to be administered before worthwhile activity is obtained.

Table 1. COMPARATIVE ACTIVITY AND MAMMALIAN TOXICITY OF VARIOUS FASCIOLICIDES FOLLOWING ORAL ADMINISTRATION TO RATS AND MICE

Fasciolicide	Fasciocidal activity* 'Adult' fluke (rats)	'Immature' fluke (mice)	Toxicity (approx. $L.D._5$ in rats)
Carbon tetrachloride	250	No action†	8 g/kg
Hexachloroethane	250	No action	6 g/kg
1.1:1:2 Tetrachloro-2,2-difluoroethane	500	No action	> 8 g/kg
1:4-*bis*-Trichloromethyl benzene	100	No action	6 g/kg
2-Hydroxy-3,4′,5-tribromobenzanilide (3 parts) + 2-Hydroxy-4′,5-dibromobenzanilide (1 part) (Mixture)	100	200 × 2 (100 × 3 no action)	600 mg/kg
2,2′-Dihydroxy-3,3′,5,5′,6,6′-hexachlorodiphenylmethane	10	100 × 1 (50 × 3 no action)	100 mg/kg
2,2′-Dihydroxy-3,3′,5,5′,6-pentachlorobenzanilide	15	100 × 3	1 g/kg

* Activity expressed as lowest dose in mg/kg showing definite action.
† Highest dose tested was 1 g/kg administered on three successive days.

A number of possible reasons for the relative resistance of 'immature' flukes to 2,2′-dihydroxy-3,3′,5,5′,6-pentachlorobenzanilide have been examined. Experiments showed that both 'adult' (12-week-old) and 'immature' (3-week-old) flukes are equally susceptible to the action of the compound when investigated under identical conditions *in vitro*, which suggested that the 'immature' flukes must receive some sort of 'protection' from their particular habitat *in vivo*. We know of two ways in which this 'protection' might arise. First, the drug is excreted as an active metabolite (glucuronide) into the bile duct, which provides a mechanism for it to become preferentially concentrated around 'adult' flukes inhabiting the bile duct. Secondly, the activity of the drug is considerably reduced in the presence of blood and serum, presumably by protein binding, and this could reduce its effectiveness against 'immature' flukes in the liver tissue. We do not know whether these are the only reasons for

the apparent resistance of 'immature' flukes or which is the most important.

The results in laboratory animals with this compound were so promising that it is now being extensively evaluated in sheep and cattle under a variety of farm conditions. Preliminary reports from a number of workers indicate that it may be of considerable value and, accordingly, it is being made generally available by Imperial Chemical Industries, Ltd., under the brand name of 'Zanil'.

HAEMATOLOGY

Strain and Sex Dependency of Pre-albumin in Mice

THE composition of the pre-albumin fraction in the serum of several species is known to be a hereditary characteristic[1-5], but sex dependency has not as yet been described.

We used Smithies'[6] horizontal technique of starch-gel electrophoresis in a discontinuous buffer system (*tris*, citrate, borate/borate, *p*H 8·5). In this way the pre-albumin in serum of mice was separated into three clearly distinct components (PA_1—PA_2—PA_3). We were not able to express our data on pre-albumin concentration in mg/ml., since pure PA was not available to us as a reference. Instead, measurements were taken with a densitometer after we had stained our electrophoretograms with amido black 10 *B*.

Seven inbred strains of mice were investigated: *AKR*, *BALB/c*$^+$, *CBA*, *C57BL*, *C*$_3$*H*, *CO*$_{13}$ and *RF*. Groups consisting of 25–30 males of each strain were examined. Fig. 1 shows the electrophoretic pattern of serum in the different strains of mice. PA_2 is present only in the *AKR*, *BALB/c*$^+$ and *RF* strains and is not observed in the others.

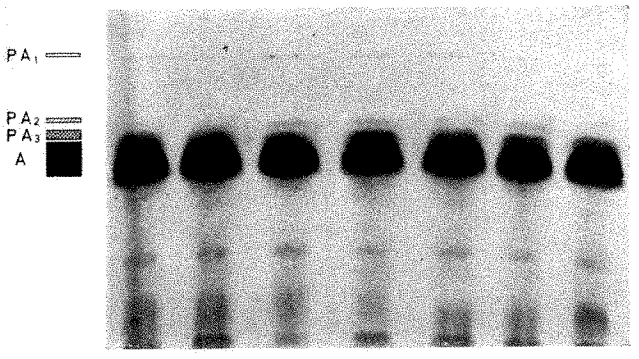

Fig. 1. Starch-gel electrophoresis of the serum of different strains of male mice. From left to right: *C57BL*, *CO*$_{13}$, *RF*, *AKR*, *C*$_3$*H*, *BALB/c*$^+$ and *CBA*

The electrophoretic pattern of female mice is significantly different from that of the males. As Table 1 shows, PA_1 is detectable only in male mice and PA_2 and PA_3 are significantly lower in females (55 per cent and 52 per cent for PA_2 and PA_3, respectively, of that of male mice).

Table 1. SEX DEPENDENCY OF PRE-ALBUMIN

Sex	No. of animals	PA_1	PA_2	PA_3
Adult male	17	7·7 ± 0·7	21·5 ± 1·5	66·5 ± 2·9
Adult female	16	Not detectable	11·2 ± 0·7	36·4 ± 1·2
Immature male	9	Not detectable	13·7 ± 1	43 ± 2
Immature female	9	Not detectable	13·5 ± 1·1	36 ± 1·6

Mean values are presented expressed in arbitrary densitometric units ± standard deviation of the mean.

No significant differences were detected in the electrophoretic patterns of immature 4-week-old male and female mice, but they are different from adult females.

We are at present investigating the influence of sex hormones on the concentration of pre-albumin in the serum of mice.

Aggregation of Human Platelets by Dextrans

DURING the course of an investigation into the effect of dextrans on platelet aggregation induced by adenosine diphosphate, it was noted that the addition of dextrans of various molecular weights to platelet-rich citrated human plasma *in vitro* resulted in a fall in the optical density of the plasma. This effect has been examined using a turbidimetric method[1] and also phase-contrast microscopy.

Blood was obtained from normal volunteers by atraumatic venepuncture using siliconized S.G. 20 needles, plastic tubes containing 3·8 per cent sodium citrate, one part citrate to nine parts blood, and was centrifuged at 190*g* for 10 min to give platelet-rich citrated plasma (PRCP) which was used within 3 h. 2-ml. portions of PRCP were placed in siliconized glass cuvettes and were stirred with polythene-covered magnetic stirrers. The optical density of the PRCP was measured at room temperature in an EEL titrometer using a red filter (608). 20 per cent solutions of dextrans of various molecular weights were prepared in 0·895 per cent sodium chloride.

The addition of dextran to a final concentration of more than 0·5 per cent to PRCP results in an immediate optical clearing effect larger than the dilutional fall in optical density, produced either by the addition of similar volumes of isotonic sodium chloride to PRCP, or of dextran to platelet-free plasma. Resuspension of the isolated platelet button in the platelet-free plasma restores the effect just described. The effect is also seen after the addition of dextrans to suspensions of washed platelets in a saline–*tris* hydrochloride buffer solution.

Table 1. MEAN PERCENTAGE FALL IN OPTICAL DENSITY AFTER THE ADDITION OF 0·2 ML. OF 20 PER CENT SOLUTIONS OF DEXTRANS OF VARIOUS MEAN MOLECULAR WEIGHTS IN ISOTONIC SALINE, AND OF 0·2 ML. SALINE ALONE TO 2·0-ML. PORTIONS OF PRCP*

Additive	No. of exps.	Mean % fall in *O.D.*
*D*10†	22	18·8
*D*20	19	19·0
*D*40	21	20·1
*D*80	20	21·8
*D*110	19	20·2
*D*150	19	16·6
*D*250	21	16·6
*D*500	22	17·0
Sodium chloride 0·895%	17	8·1

* Final dextran concentration 1·82 per cent.
† *D*10, Dextran with mean molecular weight of 10,000; *D*20, dextran with mean molecular weight of 20,000, etc.

Examination of small aliquots of PRCP and of platelet suspensions before and after the addition of dextrans, using phase-contrast microscopy and siliconized microscope slides and coverslips, confirms that dextrans produce platelet aggregation *in vitro* (Figs. 1 and 2). The degree of platelet aggregation, according to changes in optical

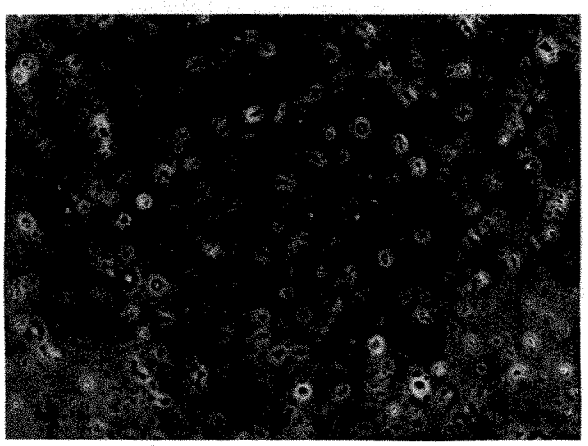

Fig. 1. PRCP before addition of dextran (phase-contrast microscopy, × c. 255)

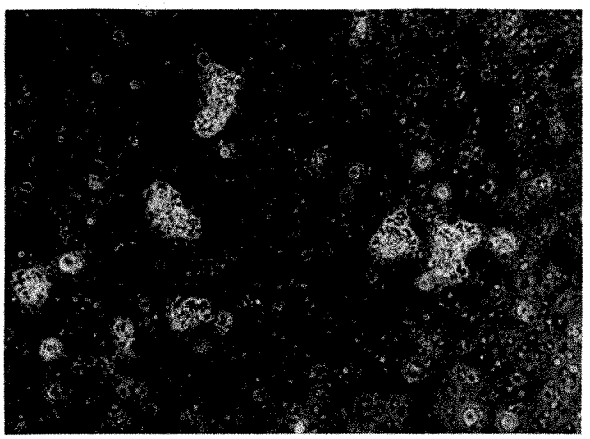

Fig. 2. PRCP after addition of dextran with mean molecular weight of 40,000; final concentration 1·82 per cent (phase-contrast microscopy, × c. 255)

density, increases with increasing concentrations of dextran, but seems remarkably independent of molecular weight (see Table 1). However, after the addition of dextrans to plasma, measurements of optical density are complicated by the precipitation of dextran–protein complexes. This effect increases with increasing molecular weight, and at the upper end of the molecular weight range of dextrans studied the net change in optical density is a summation of the optical clearing effect from platelet aggregation, and of the increased turbidity produced by protein precipitation. Thus, precise dissection of the relationship between platelet aggregation and molecular weight requires further investigation using protein-free platelet suspensions.

Previous workers have reported release of histamine from platelets by dextran[2], possibly through damage to the platelet cell membrane. Pharmacologically active substances released in this way could cause platelet aggregation, but our preliminary findings show that dextran-induced platelet aggregation is probably not mediated by any of the known chemical inducers of platelet aggregation. Dextran-induced aggregation is not spontaneously reversible on observation for up to 6 h, and slowly increases over this period; it is qualitatively different from that induced by ADP and is not inhibited by adenosine, diphenhydramine, promethazine, mepyramine maleate, imipramine or phentolamine, even in very high non-pharmacological concentrations.

We have observed a similar phenomenon with other macromolecular colloids, and early investigations of the toxicity to animals of dextran sulphate mention a platelet agglutinating activity[3]. Dextran and other colloids may induce platelet aggregation either by their adsorption on to the platelet surface or by producing physical changes in the 'atmosphere plasmatique'.

It is evident that platelet aggregation is induced *in vitro* by dextran fractions similar to those used clinically to expand the plasma volume and to improve capillary blood flow[4] and at dextran concentrations that can be attained in the blood after infusion. Further investigations to confirm that dextrans also induce platelet aggregation *in vivo* are being undertaken. The possible relationship between dextran-induced platelet aggregation and the known antihaemostatic properties of dextran remains speculative.

The dextran fractions were kindly supplied by Pharmacia (G.B.), Ltd.

IMMUNOLOGY

Antibody Nature of the Inhibitor to Antihaemophilic Globulin (Factor VIII)

ABOUT 5 per cent of haemophilic patients develop in their blood an inhibitor to factor VIII. The most likely explanation is that this is due to an immunological response to antihaemophilic factor of human origin given therapeutically on some previous occasion, since most haemophilic patients receive multiple transfusions of human blood or plasma; but development of an inhibitor is comparatively rare and therapeutic use of factor VIII of animal origin does not increase the incidence. A similar inhibitor is known as a rare complication of other conditions in patients with no previous history of haemophilia or transfusion. No direct cause-and-effect relationship between intravenous therapy and development of inhibitor has ever been established. For these reasons, and partly because of the uncertainty as to whether the inhibitor acts in the manner of an enzyme or an antibody[1,2], there has been doubt about the antibody nature of inhibitor.

The purified inhibitor was found to be associated with immunoelectrophoretically medium fast 7*S* γ-globulin[3], as had been found for reaginic antibodies involved in asthma and hay fever[4] which were later identified as IgA-antibodies[5,6]. The greater heat stability of the inhibitor and differences in the conditions of elution from DEAE-cellulose distinguish it from reagins.

In view of the controversy concerning the mode of action of inhibitor, and because of the possibility that even our most highly purified inhibitor preparations could have contained plasma components other than medium fast γ-globulin, it seemed important to establish conclusively whether the inhibitory activity could be identified with the medium fast γ-globulin in these purified inhibitor preparations. Attempts were therefore made to precipitate the inhibitory activity by rabbit antiserum specific for human γ-globulins.

Our starting material was serum from a haemophilic patient described by Hall[7] (case 1). Coagulant proteins were removed by absorption with barium sulphate and the inhibitor was purified according to Leitner *et al.*[8] and finally concentrated by ultrafiltration (to a final solution having $E^{280m\mu}_{1\,cm} = 3{\cdot}0$).

The rabbit antiserum *R*92 was prepared by repeated multiple injections of immuno-electrophoretically pure

human IgG-globulin[8] and gave on immuno-electrophoresis against whole human serum never more than the characteristic single IgG line. *R*92 thus possessed antibodies only for IgG-globulins although being capable of precipitating IgA- and IgM-globulins, since these share determinants with IgG-globulins[8,9].

*R*92 and a control normal rabbit serum of similar age and stored in the same way were both pre-treated with barium sulphate to remove the coagulation factors (barium sulphate was added to each serum sample at a concentration of 100 mg/ml.; both samples were incubated at 37° C for 15 min with constant agitation; the barium sulphate was then spun off).

The inhibitor preparation was divided into two portions of 0·5 ml. each and rabbit anti-IgG-serum *R*92 was added to one portion in four successive amounts of 0·1 ml., until only a trace of γ-globulin remained; like amounts of control rabbit serum were added to the other (control) portion of inhibitor. The resultant supernatants were examined immuno-electrophoretically and for inhibitor potency against factor VIII of human and bovine origin. Immuno-electrophoresis showed that all but a trace of γ-globulin had been specifically removed by *R*92 from the inhibitory preparation, leaving the other serum proteins intact. Table 1 shows that the anti-IgG-antiserum had

Table 1. INHIBITOR POTENCY OF SUPERNATANTS AFTER TREATMENT WITH RABBIT SERA

Pre-treatment of inhibitor	Potency* of inhibitor (units per ml.) Against human factor VIII	Against bovine factor VIII†
With rabbit antiserum for human γ-globulin (*R*92)	0·6	2·1
With normal rabbit serum	26·0	13·3

* Assay method of Biggs and Bidwell (ref. 10).
† Supplied by Maws Pharmacy Supplies, Ltd., Barnet.

likewise removed most of the inhibitor potency. The possibility remained that the inhibitor might have been absorbed non-specifically on an antigen–antibody precipitate. To test this, a precipitate of egg albumen-rabbit anti-egg albumen was formed in the presence of inhibitor. There was no diminution in the inhibitor potency when compared with a control using normal rabbit serum. (The rabbit sera were pre-treated with barium sulphate as before.)

The near-quantitative removal of IgG-globulin by *R*92 in parallel with the near-quantitative removal of inhibitor, together with the fact that the inhibitor is potentiated by therapy with factor VIII, makes it highly probable that the inhibitor is indeed an antibody. The possibility of the inhibitor being a γ-globulin with enzyme activity cannot be excluded, but seems now somewhat unlikely.

Antigenicity of Soluble Protein in the Presence of High Levels of Antibody : a Possible Mode of Action of the Antigen Adjuvants

IN experiments carried out to elucidate the mode of action of depot-forming antigen adjuvants, such as alum and mineral oil, several attempts[1,2] to mimic a slow release mechanism have been made by injecting daily doses of the antigen alone. The antibody responses obtained have, however, been found to be inferior to those stimulated by a single dose of the antigen with adjuvant. In these tests the quantity of antigen injected daily was relatively large; the total quantity given over a short time being arranged to be at least equal to a normal single dose given with adjuvant.

During recent work[3] with water-in-oil emulsion adjuvants it became evident that the antigen persisted in an active state within the emulsion at the injection site for very long periods, possibly years. The daily rate of release, if any, must therefore be very small and it was questionable whether it could be effective as an antigenic stimulus. To examine this, ten mice in a group were each injected subcutaneously with very small daily doses of antigen, chromatographically-purified ovalbumin[3], in saline. Doses of 64, 32, 16, 8, 4 and 2 μg were given successively over the first 6 days and thereafter 1 μg each day. On the fiftieth day, by which time a total of 171 μg of ovalbumin had been given, the injections were stopped.

The titre of antibody in individual samples of serum collected at intervals from the mice was measured by the tanned red cell haemagglutination test[4]. The geometric means of these titres and the response of a group of ten mice, each of which had been given a single dose of 2,000 μg of ovalbumin in a water-in-oil emulsion, are shown in Fig. 1. The very tiny doses of ovalbumin were as effective in stimulating antibody production as the much larger dose with adjuvant, even though the later injections were made into a highly immune animal. In particular, their activity is confirmed by the rapid fall in antibody level which occurred as soon as the injections were stopped.

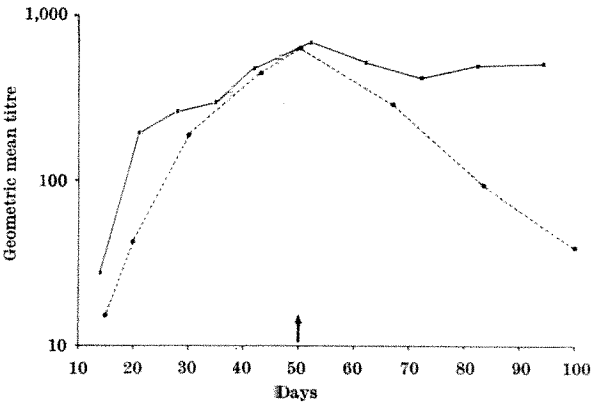

Fig. 1. The antibody responses of groups of mice inoculated subcutaneously with ovalbumin either in a water-in-oil emulsion, or as very small daily doses in saline. ——, 2,000 μg in water-in-oil emulsion; - - - -, 171 μg in saline, in divided doses, last dose at the arrow

The 2,000-μg dose of antigen given in the water-in-oil emulsion was a standard one, chosen as being the smallest which, if given in saline alone, would stimulate a measurable antibody titre. The peak antibody titre reached by mice at about the twentieth day after inoculation of 2,000 μg of ovalbumin in saline alone was less than 10 on the scale of Fig. 1. Smaller single doses of antigen given in saline or in water-in-oil emulsion produced lower peak titres and there was no evidence of any immunological paralysis at the standard dose level.

The excellent antibody response obtained by giving very small daily doses of antigen indicates that a slow release mechanism could fully explain the great effectiveness of the

depot-forming adjuvants. These results also show that a very tiny quantity of antigen, which must presumably combine with antibody immediately after injection, is still able to stimulate further the antibody-forming cells.

This investigation was supported by the Animal Health Trust.

HISTOCHEMISTRY

Histochemical Observations on the Lipids of Carious Human Dentine

THE presence of lipids in carious dentine has been observed, and variously considered to be of exogenous[1] or endogenous[2,3] origin, and the staining of the peritubular dentine matrix of sound dentine by histochemical techniques for lipids has been reported earlier[4].

Undecalcified ground sections of dentine, approximately 7μ thick, were prepared from human molar teeth exhibiting occlusal Class I type caries. Sections were cut through the lesion transverse to the long axis of the tooth. The caries was thus completely surrounded by sound dentine, which provided reference and support and the maximum number of tubules were cut transverse to their long axis. The centre of the lesion was its most advanced part and its periphery the advancing front. Some sections were unfixed, being prepared under iced saline; others were fixed in 10 per cent neutral formol saline or 70 per cent ethyl alcohol. Sections were stained without further treatment, or after being subjected to boiling 0·02 per cent acetic acid for 8 min. The staining methods employed were: acetone sudan black *B*[5], phosphomolybdic acid[6], nile blue sulphate[7], and Luxol fast blue[8].

After unmasking in acetic acid, dentine sections exhibited a periphery of sound dentine in which the peritubular matrix was well stained but the intertubular matrix was unstained. At the junction with the carious lesion, the staining of the peritubular matrix increased in density, and in the more advanced parts of the lesion the intertubular matrix stained with increasing intensity, until, at one level, the peritubular and intertubular matrices stained equally. With further progression of the caries the peritubular matrix became unstained, so that the appearance was the reverse of that seen in sound dentine. In the centre of the lesion no stain was retained by any part of the dentine. Similar sections, stained without previous unmasking in acetic acid, did so in a comparable manner, but the carious dentine tended to retain more stain, consequently the differentiation of the various zones was not so evident. The sound dentine, apart from the tubule contents, remained unstained. At the advancing front of the lesion the peritubular matrix was heavily stained; at a deeper level the intertubular matrix also stained, and with increasing intensity.

It appears that the carious process first unmasks the lipids present in the peritubular matrix, as shown by its heavy staining. This unmasking is accompanied by a partial release of these lipids, as following hot acetic acid they are unstained in the more advanced parts of the lesion. Comparable changes in the staining of intertubular dentine matrix, though phased later, presumably indicate the presence of lipids. However, probably because suitable unmasking techniques have not been utilized to date, they have not been convincingly demonstrated in this matrix in sound dentine.

This evidence, showing that the development of lipid staining in carious dentine follows a similar pattern to that which can be obtained in sound dentine, suggests that much of the lipid component of caries is of intrinsic origin, though it does not exclude the possibility of an extrinsic component as well.

RADIOBIOLOGY

Relation between Extrapolation Number and Apical Cell Number in Gemmae of *Marchantia polymorpha* L.

THE gemmae of *Marchantia polymorpha* L. are approximately discoidal with two apical notches 180° from each other[1,2]. An apical notch marks the location of paired apical cells. Radiobiological data on gemmae of *Marchantia* indicate that the apical growth of a gemma need not necessarily be the only type of growth occurring in the proliferation of a viable outgrowth from a gemma[3–5]. In addition, it has been shown that cell survival within the irradiated gemma is correlated with nuclear volume differences among the different cells[4,5]. These results are similar to those reported for the radiosensitivity of 'higher plants' by Sparrow and co-workers[6–8], Osborne *et al.*[9,10], and Lunden[11], although the former authors[6–8] state that the volume of the chromosome at interphase is a better index of radiosensitivity than nuclear volume.

The present investigation was conducted in an attempt to determine whether or not the production of a viable apical outgrowth from an irradiated gemma is dependent on the destruction of both apical cells.

Gemmae of *Marchantia* were irradiated with 250 kVp. X-rays and aseptically cultured according to a previously published method[12]. At the control and lower exposures 130 gemmae were used for each treatment; at the 35·8 kr and 39·4 kr exposures 2,080 gemmae were used for each exposure. The percentage apical survival for each treatment was plotted against exposure on a semilog graph (Fig. 1) according to the method of Atwood and Norman[13]. The survival curve in Fig. 1 is sigmoid and fits the expression $S = 1-(1-e^{-kD})^n$ where S is the survival at dose D, n is the extrapolation number that can represent the number of sites (or cells) of a particular type that must be inactivated in order to halt the increase in cell number[13]. This parameter, n, may be determined by extrapolation of the exponential portion of the survival curve if survival is plotted against dose on semilog paper, or it may be computed according to the equation $\log S = \log n - kD$ (see derivation in Atwood and Norman[13]). Extrapolation of the straight line portion of the curve in Fig. 1 to $D = 0$ gives $n = 2{\cdot}7$. A t-test showed this number not to differ significantly from 2 or 3 at the 5 per cent level, but to differ significantly from 1. Thus, the survival curve for apical survival gives an extrapolation number of approximately 2, which on a target hypothesis indicates that both apical cells must be inactivated in order to stop apical growth of a gemma.

Additional research has shown that both apical cells are active in DNA synthesis and mitosis. These results tend to support further the idea that both apical cells

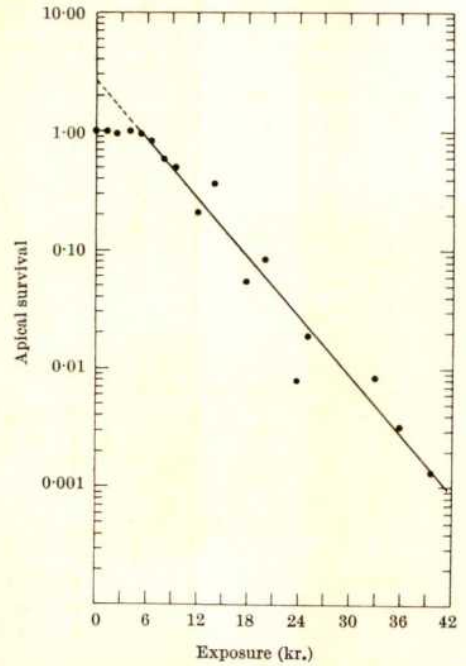

Fig. 1. Radiosensitivity of the apical notch to acute gamma irradiation. Measurements for survival of the apical notch were made at the end of one week of growth. The linear portion of the curve is extrapolated to D (exposure) = 0. Log $Y = 0{\cdot}43746 - 0{\cdot}08296\ X$

must be inactivated to halt apical survival. Further investigations are now in progress.

Ultrastructural Aspects of Duodenal Crypts in X-irradiated Mice after Chemical Protection

AFTER X-irradiation the cells of the duodenal crypt of the mouse show morphological alterations which have been described with the help of optic and electronic microscopy[1,2]. The protective effect of aminoethylisothiourea (AET) on the intracellular structures of the irradiated duodenum has already been shown[3]. Recently, it was demonstrated by different authors that a mixture of certain radioprotectors was more effective than each alone[4,5] and even allowed an increase of the *L.D.* 100/30 by a factor of 2·4 (ref. 6). With these results in mind, we have investigated the ultrastructural aspects of the duodenal crypt after irradiation of mice protected by a mixture of glutathione, AET and serotonin.

BALB/c[+] adult male mice were given intraperitoneally 16 mg glutathione per os, 8 mg AET and 1 mg serotonin, 25, 10 and 5 min before irradiation respectively. Other mice were injected, before irradiation, with AET alone and some were irradiated controls. The conditions of irradiation were: 1,350 r., 200 kV, 10 m.amp; dose-rate, 100 r./min. The animals were killed 30, 60, 180 and 300 min after irradiation. A small piece of duodenum was immediately fixed in 2 per cent osmium tetroxide and embedded in 'Epon'.

We report here the first results we obtained of the modifications of the stem cells of the duodenal crypt. We found that the irradiated non-protected mice showed a dilatation of the mitochondria after 30 min; the number of lysosomes increased after 60 min and big cytolysomes were obvious in almost all the stem cells after 180 min[2].

The AET-protected irradiated mice exhibited some delay in the appearance of the lesions; the dilatation of mitochondria was not visible before 60 min and later was less important than in irradiated controls. It must be noted, however, that after 300 min many cytolysomes were present in the stem cells (Fig. 1).

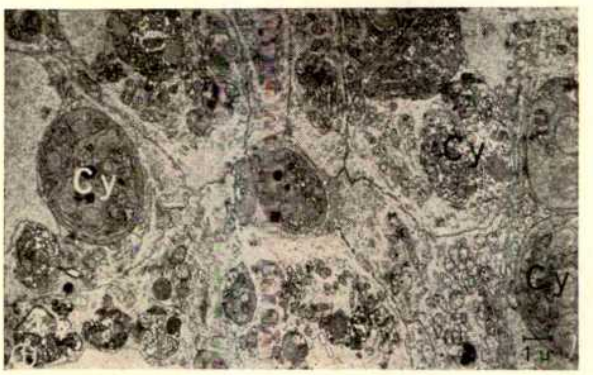

Fig. 1. Duodenal crypt 6 h after 1,350 r. in an AET-protected mouse. Many cytolysomes (*Cy*) in the stem cells (×*c.* 2,465)

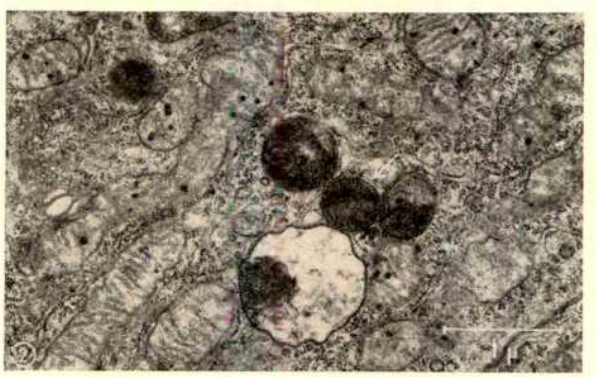

Fig. 2. Part of a stem cell 6 h after 1,350 r. in a mouse protected by the radioprotective mixture. Four vacuoles with dense or clear content; arrow points to vacuole with needle-shaped structures (×*c.* 14,815)

The irradiated mice protected by the chemical mixture did not show, even after 180 min, any important mitochondrial dilatation, but the mitochondria were twisted and elongated with shadowed cristae and frequently presented a shrinkage; after 300 min, the number of cytolysomes was still very low; at this time, in the vicinity of the Golgi zone, many clear vacuoles with a granular or fibrillar content were found; other vacuoles exhibited a dense matrix with needle-shaped structures (Fig. 2); these organites were never seen in the controls and were uncommon in animals injected with AET alone; these structures were also numerous in the non-irradiated mice injected with the mixture

The protection of the undifferentiated stem cells of the duodenal crypt at the ultrastructural level seemed to be,

in the first hours after 1,350 r., very important after the use of this chemical mixture.

It is possible that the needle-shaped structures in vacuoles, described 300 min after administration of the protectors, are formed by the collected metabolites of the injected drugs through a similar process of the accumulation of 'Triton' in the hepatocytes of the rat[7].

BIOLOGY

Cell Cleavage in Polar Body Formation

THERE has been widespread acceptance of the generalization formulated by Conklin[1] and Wilson[2] that, when mitosis is followed by normal cytokinesis in plants and animals, the "cleavage takes place in a plane approximately at right angles to the spindle axis and primarily across its equatorial plane"[2]. (In certain cells which are large in comparison with the mitotic apparatus, the equator of the spindle becomes a part of the cleavage surface, but the latter may curve on either side of the spindle.) The generalization has been shown to be true for all cases of cytokinesis which have been studied intensively[3]. Moreover, after the nucleus has been displaced by experimental means, the subsequent cleavage has occurred through the middle of the spindle wherever the spindle might be at the late anaphase stage[1,4–8].

Polar body formation is an extreme case of unequal cleavage and so it affords a useful test case for theories of cleavage. A recent reviewer states that "it is one of the few cases in which the cleavage plane does not bisect the metaphase spindle"[9]. This statement does not contradict the generalization of Conklin and Wilson because it is the telophase spindle rather than the metaphase spindle which is bisected by the cleavage furrow. Conklin showed that in the normal maturation divisions of eggs of the gastropod *Crepidula* "the division wall forms through the equator of the spindle"[1]. In polar cleavages the spindle moves with respect to the egg surface between metaphase and the stage at which cleavage is completed. For the case of the *Cerebratulus* egg[10], the *Limnaea* egg[11], and other eggs for which the polar metaphase spindle is oriented radially at the egg surface[2], there is a translational movement of the spindle parallel to its axis and outwards from the egg centre. This is accompanied by a cleavage for which the astral relaxation theory has been proposed[9]. The theory postulates that the aster differentiates the cell membrane opposite it, where a local weakening in the consistency of the cell surface allows internal pressure to push out the polar body from the egg.

More recently, observations have been made on the formation of the second polar body of certain rodent eggs *in vitro*[12–14]. This work seems to have passed unnoticed by students of the mechanism of the cleavage process. Excellent photographs by phase-contrast microscopy show that, for eggs of the rat and the hamster, the cleavage surface grows through the mid-point of the spindle and, in so doing, bisects that aggregation of granules found at the equator of the spindle which is sometimes called the intermediary body or the mid-body. Although in certain optical microphotographs, such as Fig. 10 of Austin[13] and Fig. 5 of Odor and Renniger[15], the cleavage furrow appears to have passed just to one side of the intermediary body so that it is included in the polar body, by electron microscopy the new plasma membrane appears to be derived by the coalescence of vesicles located down the mid-line of the intermediary body[15]. The optical microscope appearance may be an illusion due to the optical depth of focus being greater than the thickness of the ultra-thin section required for electron microscopy. The cleavage furrow is initiated at the egg surface where it is first close to the equatorial plane of the spindle when the latter is in its initial chordal position (Fig. 1*a*). As the spindle pivots about one pole to assume a radial orientation with respect to the egg surface, the newly formed furrow grows through the cytoplasm in the path of the intermediary body (Fig. 1*a*, *b* and *c*). The photographs of Austin[12] were taken with the egg flattened between slide and coverslip so as to observe greater detail. Under these conditions cleavage is not completed and the path of the furrow is more deeply indented into the vitellus than would be the case for an uncompressed egg, such as that shown in Figs. 10 and 18 of Austin and Walton[16]. Other features of the polar cleavage described above are not affected by the compression. To the extent that the polar cleavage of these rodent eggs appears to be initiated at or near the equatorial plane of the spindle, and to grow from the egg surface through the cytoplasm, it appears to resemble the first zygotic cleavage of newt[17], axolotl[8] and sturgeon[8]. The astral relaxation theory does not adequately explain the polar cleavages in eggs of rodents.

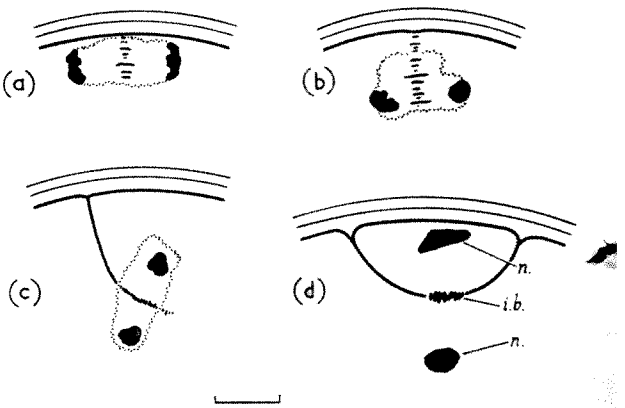

Fig. 1. Stages in the formation of the second polar body in the rat egg, traced from the microphotographs of Austin (ref. 12) (*a*, *b* and *c*) and Austin and Braden (ref. 14) (*d*); (*n*, nucleus, *i.b.*, intermediary body). *a*, *b* and *c* are from continuous observations made on a single egg. The scale represents 10μ

Several lines for future experimental work suggest themselves. It may be possible to measure changes in the optical properties of the cell membrane during polar cleavages and to compare the results with those obtained for the first zygotic cleavage of the sea-urchin egg[18]. Recently, improved methods of fixation for electron-microscopy have revealed greater ultrastructural detail within the intermediary body of dividing HeLa cells[19,20] and similar techniques should now be applied to eggs in polar cleavage. By these methods and by micrc manipulation it may be possible to obtain evidence for the existence of connexions between the mitotic apparatus and the inner layers of the egg cortex and this would throw light on the observed spindle movements.

I thank Dr. C. R. Austin for commenting on this letter and for permission to publish diagrams from his photo-

graphs. I also thank Dr. R. A. Beatty for discussion, and Prof. C. H. Waddington for his interest.

Oxytocin and the Life-span of Male Rats

Friedman and Friedman[1] recently reported that chronic administration of a crude extract of the posterior pituitary gland extended the life-span of old male rats. They postulated that this effect resulted from changes caused by vasopressin in the metabolism of water and salts. Vasopressin alone, however, failed to produce prolongation of life in the aforementioned experiments. More recently, they have extended their investigations to the effect of aldosterone.

It seemed to us not unreasonable to assume that the effect on life span of posterior pituitary extracts is attributable, at least in part, to their content of oxytocin rather than of vasopressin. The possibility that a third, perhaps yet unknown, factor is present in the gland has not been overlooked.

In the investigation reported here, male Sprague-Dawley rats were used (*C-D* strain, obtained from Charles River Breeding Laboratories), which were 15 or 16 months old at the start of the experiment. Animals of approximately equal weight (within 15 g) and in apparent good health were selected and divided at random into three groups of twelve rats each. Rats in each group were given subcutaneous injections three times a week. One group received 1 U/kg of posterior pituitary extract prepared by suspending 'Powder Posterior Pituitary U.S.P.' (Lilly) in saline. The second group received 1 U/kg of synthetic oxytocin, 'Syntocinon' (Sandoz), diluted in saline, and the control group was treated with saline.

While no significant difference was observed between the number of surviving rats in either of the two treated groups and those in the control group during the early months of the experiments, after a year a difference was apparent. The results of our investigations are summarized in Table 1, which shows the number of survivors at the end of each month of the experiment.

Our experiment seems to confirm the findings of Friedman and Friedman concerning the life-prolonging effect of the chronic administration of posterior pituitary extract in the rat but, at the same time, points to oxytocin as the most probable factor responsible for this phenomenon. It seems to be quite possible that oxytocin, in addition to being a hormone which causes ejection of milk and contraction of the uterus, may have also an as yet undisclosed, more general role in the life processes. Its occurrence in the male and in non-mammals is also suggestive in this respect.

Table 1. NUMBER OF RATS SURVIVING AT THE END OF EACH MONTH

Peritrophic Membranes in Arachnida (Arthropoda)

PERITROPHIC membranes have been studied in insects from the microscopic[1], submicroscopic[2] and histochemical[2–4] point of view. The lack of information about this structure in arachnids has already been emphasized[5,6]. I therefore present some more bibliographical and histological data on this subject.

Tulk in 1843 (ref. 7) gives a description of a membrane which completely surrounds the excreta in the stomach in *Phalangium opilio* (Latr.). Plateau[8] indicates some of the chemical properties of such a membrane in the distal part of the midgut in *Agelena labyrinthica*, and presents figures of a membrane that envelopes the excrementa of *Argyroneta* and *Epeira umbratica* (these three species belonging to the Araneidae). The histological work of Millot[9] on spiders also gives a description of a basophil membrane, formed by the fusion of distinct droplets round the excrements in the midgut, just behind the outlet of the abdominal diverticulae. This author gives no details concerning the species in which he observed the membrane. De Mets[5] gives electron microscopic figures of the peritrophic membrane in the horseshoe 'crab' *Xiphosura polyphemus*, whereas Grainge and Pearson[6] describe a membrane of 0·5μ thick in some Phalangidae.

I observed a peritrophic membrane in the cloaca (Fig. 1) and the midgut (Fig. 2) of *Linyphia triangularis* (Cl.), (Araneidae), a web-spinning spider, as well as in the postdiverticular midgut of the garden-spider *Araneus diadematus* (Cl.) (Fig. 3).

The histological preparations (fixation in Bouin and paraffin sections of 8μ) are stained with haematoxylin at *p*H 3 and potassium alum, and counterstained with erythrosine. The blue colour of the peritrophic membrane contrasts with the reddish base-tone of the gut contents and excrements and indicates their basophilic nature. Its

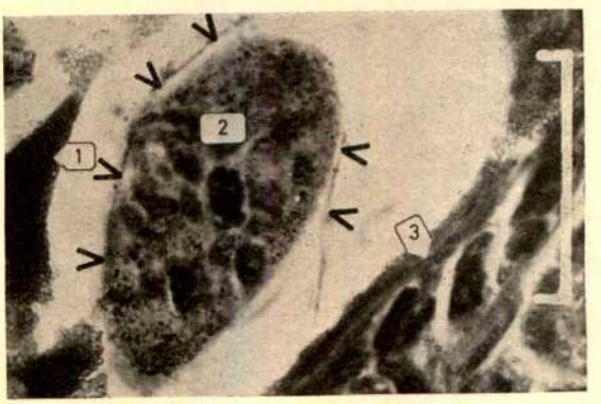

Fig. 1. *Linyphia triangularis:* guanine excretion (1); faecal pellet (2) with cellular debris; cloacal wall (3). The 'V' signs point to the peritrophic membrane. Scale = 50μ

thickness lies on the limits of optic resolution in *L. triangularis* (*c.* 0·4μ).

Some preliminary electron microscopic observations on the membrane that surrounds the faecal pellets (Fig. 4) in the cloaca of this species confirm this thickness, and suggest the composite nature of the membrane. The inner part presents a folded surface, the outer part being rather smooth and sometimes being loosened from the inner membrane (possibly due to stress during preparation: fixation in osmium oxide, embedding in 'Araldite' and sectioning with glass knives).

The complete lack of any experimental evidence for hypothetical functions of this membrane in digestion and/or excretion, in insects as well as in spiders, might stimulate physiological research into this matter.

I thank Dr. J. Hugon for the electron microscope photographs. This work was supported by grants from the Belgian Fund for Joint Fundamental Research.

Light Measurements in Plant Growth Investigations

THE procedure suggested by K. J. McCree[1] under the above heading would only be of use if it were intended to estimate plant growth from the time-integrated values of the transformed light measurements, and in view of the many assumptions involved it would then seem more sensible to measure the growth directly. He implies that the object of measuring daylight as a part of the microclimate of the plant is to obtain a good correlation (that is, a linear relation) between the light measurement and growth and that the ideal would be if "the response of the photocell were to be made to match that of the plant before the integration was performed". However, as he truly writes: "Though the actual relationship may vary with type of plant, the stage of growth and the growth conditions, it will practically never be linear". It is in fact just the study under natural conditions of the departures from linearity of these relationships that provides the usual reason for measuring daylight, and this study becomes impossible if an empirical transformation, based on data obtained under other growth conditions, is used as suggested by McCree. An integration with respect to time of the daylight measured on a linear scale during a period gives an unequivocal value for the amount of light available and the response of the plant during that period shows the use it makes of this under natural conditions. The response will depend on the variation in light intensity in the period, which is one of the natural conditions involved.

It is obvious that the curvilinear relationships between amount of light and plant responses can only be estimated with much precision by holding the light intensity constant at various levels for a sufficiently long period for the responses to be measured at each. This is usually impossible under natural conditions and the best that can be done is to integrate the daylight over the shortest periods suitable for measuring the particular plant response concerned. In this way approximate relations can be obtained without question-begging and can be compared with those found under controlled conditions, which are necessarily in some respects remote from the conditions found in nature. Information on the range of light intensity in each period might well assist interpretation.

It is to be expected that by no means all plant growth responses to light will show a good correlation with carbon dioxide uptake, and in McCree's system it would be necessary to use different transformations not only for different types of plant, stages of growth and growth conditions but also for various kinds of plant response. I agree with him that "the first essential is to choose a rational basis for the measurements" but not that "the instrumental details are of secondary importance". Under natural

conditions there is so much spatial variation in light intensity, this variation itself varying in time, that it is necessary to use large numbers of detectors, which must therefore be inexpensive. The question of what range of wave-lengths to include in the light measurements is also important and must depend on a knowledge of the plant processes under investigation. However, within that range the same principle applies, that it is essential to measure light on a scale with a definite physical meaning and then compare the response of the plant with the amount of light, rather than beg the question by adjusting the light scale to some assumed plant response. Thus the measuring instrument should give as nearly as possible a constant response, preferably per quantum rather than per unit of energy, at all wave-lengths within the range included, rather than be made to follow, for example, an action spectrum for photosynthesis measured under a certain set of controlled conditions. (The confusion that this last arrangement would cause becomes obvious when it is remembered that the action spectrum changes with light intensity above the range where light is severely limiting.) Changes of light quality within the periods for which plant response is to be related to the time integral of the measured light, like changes of intensity, are likely to decrease the accuracy of the estimated relationship. Changes of quality between such periods, if they can be detected by other means and correlated with changes in the plant response to amount of light, may provide clues to be followed up by experimentation under controlled conditions.

[1] McCree, K. J., *Nature*, **206**, 527 (1965).

PROF. HEATH raises the fundamental question of the purpose of making light measurements, and I am happy to give my point of view. I think that it will eventually be possible to predict the growth rates of plants from measurements on their environments, given sufficient understanding of the principles behind the interactions between plant and environment. The models will have to be complex, because plants are complex, but this presents no difficulty to an electronic computer. The limitation is not in our ability to speculate, but in our ability to describe the principles of plant behaviour in numbers rather than in words.

As more sophisticated models of plant behaviour are developed, they must be tested at every stage against facts obtained by growing plants in the field. In experiments designed for this purpose, the climate measurements will be confined to those which the theory says are relevant. I hope there will be more of this type of field experiment in the future. Even in experiments designed to determine the growth rate of a particular plant in a particular place, where climatological data are collected only as a guide to the factors which might be influencing the growth rate, there is room for a great deal more selection of climate measurements than is common at present.

For example, it is simply not true that the departure from linearity of the relationship between growth rate and the various totals of a linear light integrator is a measure of the light response of the plant. The departure could just as well be due to water stress or abnormally high temperatures, accompanying high levels of radiation. But if one makes a quantitative allowance for the non-linearity of the plant, based on laboratory measurements of the curve for carbon dioxide uptake, then the light effects can legitimately be separated from the effects of other factors.

This quantitative allowance for the response of the plant needs to be applied before the light is integrated with respect to time. The totals of the usual linear light integrator are not sufficient; one needs information about how each total was made up. In my previous communication I indicated how this information might be collected, and we are now developing an instrument for this purpose. At the same time we are conducting experiments to find out how well the readings of such an instrument can be related in practice to the growth rates of plants.

In his discussion of 'physical' and 'empirical' scales, Prof. Heath appears to be investing physical measurements with an almost mystical significance. But even in physics, a measurement has meaning only after it has been interpreted. This is the real test of the superiority of one scale over another—take, for example, the various scales which can be used for measuring spectral colours. The physicist uses a frequency scale when he is studying photoelectric effects, because he interprets in terms of quanta; in interferometry, he uses a wave-length scale, because he interprets with the wave theory; in photometry, he uses a scale which biases the strengths of the various colours in the same way as an 'average' human eye. In the same way, when measuring light for plant growth studies, it is logical to use a scale which takes account of the photosynthetic efficiency of different colours. On any other scale, the measurements would be more difficult to interpret.

Of course, in each case it is essential that everyone should agree to use the same scale. In science, an 'interpretation' is not complete unless it can be repeated. But this is not an argument against using a scale which fits the purpose of the experiment.

I have discussed elsewhere[1] the problems of choosing and agreeing on a scale for photosynthetically active radiation. The difficulties raised by Prof. Heath are just those which were raised in the 'twenties when a photometric scale was being discussed. Yet the scale which was internationally agreed in 1931 has worked very well in practice, despite its known deficiencies—in fact, a whole branch of engineering is based on it. Since I do not believe that the human eye is inherently any less complex than the photosynthetic system of a plant, I hope it will not be too long before 'green plant engineers' will agree to adopt their own scale of light measurement. I am sure it will then be easier to interpret the measurements.

Clarity in recording Germination Data

TIMSON[1] suggests that, compared with straight germination percentages, the following procedure would provide a more meaningful evaluation of germination data: the total percentage of seeds which have germinated to date is recorded every day for a stated number of days from sowing, and these daily values are summed. Timson terms the result thus obtained from observations up to, for example, day 10, the '$\Sigma 10$'. This scheme is possibly as successful an attempt as any at producing a unified expression of two values, germination percentage and time to germination. But any such expression is apt to obscure, rather than clarify, the situation, except when germination is both rapid and high or both slow and low. For example, with two hypothetical seed samples the percentages germinating on successive days may be 40, 20, 0, 0, 0 of sample A, and 10, 30, 30, 30, 0 of sample B. Timson's $\Sigma 4$ would therefore be $40 + 60 + 60 + 60 = 220$ for A, and $10 + 40 + 70 + 100 = 220$ for B, although the two samples are dissimilar in both germination percentage and time to ultimate germination. More-

over, a shorter period of assessment would favour the faster, a longer period the more fully germinating sample: Σ3 would be 160 for *A* and 120 for *B*, whereas Σ5 would be 280 for *A* and 320 for *B*.

Even without taking percentages into account, the time to germination, the importance of which Timson stresses, is not easy to represent unambiguously. Kotowski[2] used as his "coefficient of velocity of germination" (*Cv*) the reciprocal of the weighted mean number of days to germination, which may be written:

$$Cv = \frac{\Sigma G_n.100}{\Sigma G_n.D_n}$$

where G_n is the number of seeds germinating on day D_n, and D_n is the number of days from sowing. This figure has the advantage of indicating the average time to germination irrespective of germination percentage, but does not provide any information about the uniformity of the seeds within a population: a certain average time may result, either when all seeds germinate almost simultaneously or when some do so very early but others very late. Therefore, in order that the germination pattern may be characterized more precisely, a third piece of information, in addition to percentage and average time to ultimate germination, is required, corresponding to the variance of the frequency distribution, if this were normal, of the number of seeds recorded as having germinated over successive time intervals. But the frequency distribution of times to germination even in non-dormant seed samples is not usually normal but positively skewed, and in certain ecological situations the size and shape of the 'tail' may be of considerable importance. With plants in cultivation the seed cleaning process often further modifies any pattern that may exist in a random population by eliminating a proportion of light-weight seeds.

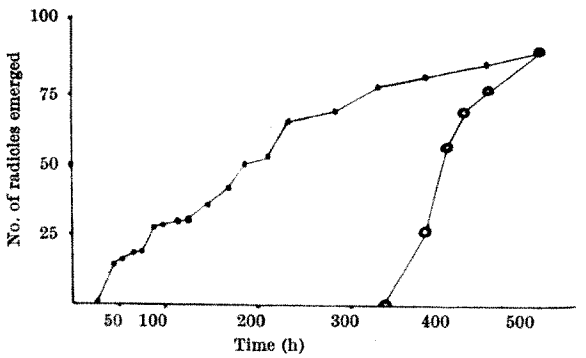

Fig. 1. Radicle emergence of lettuce seeds ('Webbs Wonderful') at 0·5° C (○), and 25° C (●). 100 seeds per 9-cm diameter Petri dish on two layers of Whatman No. 1 filter paper with 7 ml. distilled water, in the dark. Three replications

The use of quartiles, that is, times to 25, 50, 75 and 100 per cent of the ultimate number germinating, has been suggested by R. T. Clarke (personal communication) as a method of dealing numerically with such complex situations. However, cumulative curves can be very informative, even though not themselves statistically tractable.

Furthermore, the effect of environmental conditions on germination should be sufficiently stressed. It is of interest in this connexion that the same batch of seeds can differ widely, depending on the temperature, not only in its average time but also in the scatter in the time to germination. Fig. 1 presents results obtained with lettuce seeds near their minimum and maximum germination temperatures. The seeds show greater uniformity in behaviour at the cold than at the warm extreme. The genetical and ecological significance of this phenomenon is a subject for further investigation.

I thank M. A. Nichols for permission to present unpublished data.

Comparison of the Biosynthesis of Cellulose *in vitro* and *in vivo* in Cotton Bolls

THE work of Hassid *et al.*[1-3] on the cell-free synthesis of cellulose with an enzyme system isolated from mung bean seedlings and young cotton bolls has shown that the enzyme is apparently unable to distinguish guanosine diphosphate-D-glucose from guanosine diphosphate-D-mannose. Moreover, there was a notable decrease in the amount of the synthesized cellulose using enzymes from cotton bolls older than 15 days.

Lately, I have approached the biosynthesis of cellulose in higher plants from the kinetic point of view with the following results[4-8]:

(1) The biosynthesis of cellulose consists of two distinct kinetic stages. The first proceeds very slowly and yields only little cellulose, while in contrast, the second stage proceeds very rapidly and gives nearly all the cellulose produced (Fig. 1). The two kinetic periods have been correlated with the formation of the primary and the secondary cell wall, respectively.

(2) The corresponding degrees of polymerization (weight average DP_w), and its distribution at different conversions, remain constant (Fig. 1) and practically homo-

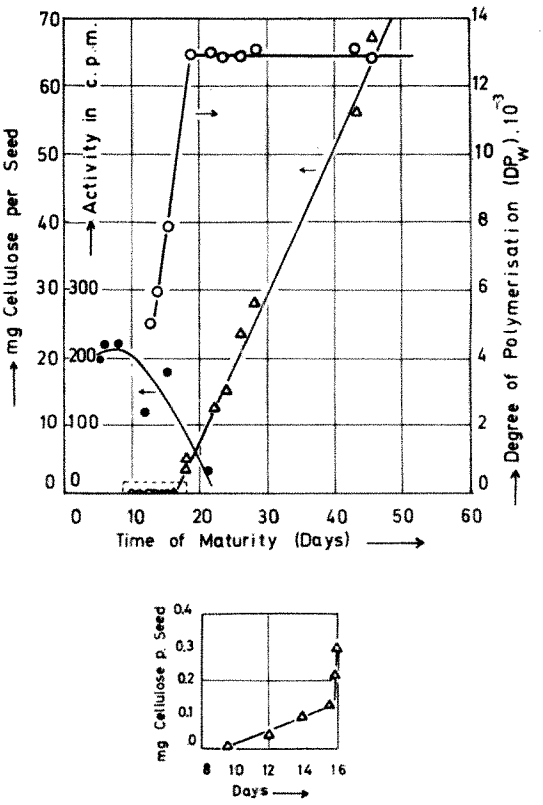

Fig. 1. Cell-free synthesis and biosynthesis of cellulose in relation to the age of the cotton bolls. ●, Cell-free synthesis according to Hassid, conversion expressed in c.p.m.; △, biosynthesis, conversion in mg per seed; ○, biosynthesis, corresponding degrees of polymerization (weight average)

geneous during the whole second reaction stage. This means that the biosynthesis of the secondary wall cellulose reacts by a structure-controlled mechanism (template mechanism).

With regard to the primary-wall cellulose I found no results which point to a similar template mechanism. The corresponding DP_w is much smaller and its distribution very broad. In this period, a high quantity of materials other than cellulose is also produced.

On the basis of these results I have formulated the following explanation for the findings of Hassid: the cell-free synthesis of cellulose by means of enzyme preparations from cotton bolls corresponds to the first reaction period leading to the primary cellulose. Since *in vivo* during this stage other compounds than cellulose are also formed, it is probable that this also happens *in vitro*. The enzyme seems to lose its activity with an increase in the age of bolls, since I have found that the synthesis of the primary cell wall is finished only a short time after the beginning of the secondary wall synthesis[6]. The enzyme responsible for the syntheses of the secondary wall cellulose may be not the same and may react only in presence of a template. Assuming that the template was not yet formed or was destroyed during preparation of the enzyme for the cell-free synthesis, one could explain the great decrease in the amount of formed cellulose using the 21-day-old cotton bolls.

Fig. 1 shows the values found by Hassid with my kinetic results. Although the conditions of growth of the cotton plants were different, the coincidence of the age of the bolls at which the cell-free synthesis loses its activity, and the biosynthesis of the primary cellulose in the cotton bolls finishes, is remarkable.

Kinetics of the Biosynthesis of Cellulose in Cotton Bolls by Different Light Intensities

PREVIOUS kinetic investigations of the biosynthesis of cellulose in higher plants suggested that the secondary wall cellulose is synthesized by a structure-controlled mechanism (template mechanism)[1–5]. In order to confirm my assumption I changed the reaction rate by varying the intensity of illumination of the cotton plants. Cotton plants (*Gossypium herbaceum*) were grown in a glass-house at a mean temperature of 25° C (the night temperatures never were less than 18° C). The intensity of illumination amounted to 4,000, 15,000 and 60,000 lux respectively (mean values). The time of maturity was calculated from the time the flowers were fertilized. Bolls of different maturities were picked, immediately opened and the seedhairs quantitatively removed from the seeds. The methods used to determine the conversion of cellulose and the degree of polymerization have already been described[1,2].

If the secondary wall cellulose is synthesized by a template mechanism, then the degree of polymerization must be independent of any variation in the kinetics. The results in Fig. 1 show that this is the case. In spite of the considerable variation of the rate of synthesis with light intensity, the degree of polymerization remains

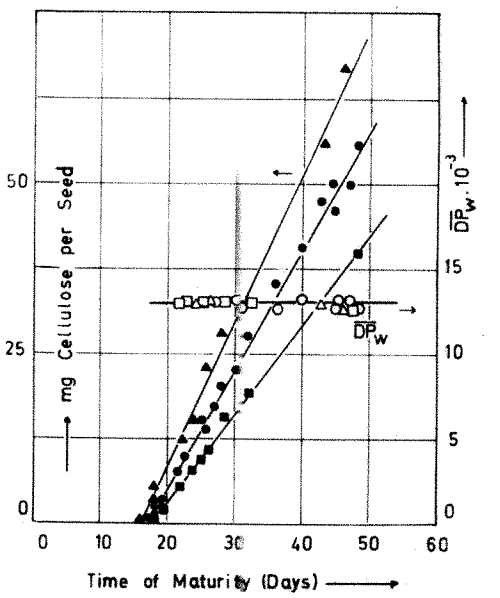

Fig. 1. mg Cellulose per seed and corresponding degree of polymerization (weight average) with time of maturity at different intensity of illumination. ▲, 60,000 lux; ●, 15,000 lux; ■, 4,000 lux; △, 60,000 lux; ○, 15,000 lux; □, 4,000 lux

constant at approximately $DP_w = 13{,}000$, independent of the conversion and the rate of synthesis.

Bromination of Fluoresceins by the Dogfish, *Squalus acanthias*

THE natural occurrence of bromo-compounds in the coral fan *Gorgonia verrucosa* and in certain species of shellfish, especially *Murex brandaris* and *M. tranculus*, is well known[1,2]. Bromination of phenol red by an enzyme system isolated from the mould *Caldariomyces fumago* has been observed[3]. *In vitro* bromination of phenol red by uterine slices and bromination of phenol red, chlorophenol red, metacresol purple and fluorescein after intra-uterine administration of these dyes to the pregnant spiny dogfish, *Squalus acanthias*, have been reported[4,5]. The work recorded here is an extension of the latter observations.

Pregnant spiny dogfish were kept in a wooden enclosure with free access to sea water at 14°–15° C. The uterine fluid was withdrawn by pipetting through the uterine pores which open into the cloaca and was replaced with a saturated solution of the dye in sea water. Various dilutions of the dyes were also used. At the end of the experiment, generally 48 h after instillation of the dye, the uterine fluid and resultant dye were easily collected by pipetting. The spectra of the dyes in the visible region before and after instillation were recorded and compared with authentic samples. Paper chromatography was performed on Whatman 3 *MM* paper in systems previously reported[4,6].

Forty-eight hours after intra-uterine administration of fluorescein, the resultant product was found to be eosin (tetrabromofluorescein). Thus, the sulphonic acid moiety present in the phenosulphone phthalein dyes, which are brominated, could be replaced by the carboxylic group

in fluorescein without loss of bromination. The following bromofluoresceins were found to be brominated to eosin 48 h after instillation in the dogfish uterus: 4-bromo, 2,4-dibromo, 2,7-dibromo, 4,5-dibromo, 2,4,5-tribromo and 2,4,7-tribromofluorescein. After intra-uterine administration of fluorescein, various bromofluoresceins (4-bromo, 4,5-dibromo, 2,4,5-tribromo and 2,4,7-tribromofluorescein) could be recovered in 6, 12 and 24 h. However, 48 h after instillation of fluorescein only eosin could be recovered. This evidence implicates a stepwise bromination by the dogfish uterus. Because of the oxygen bridge, fluorescein differs from phenosulphone phthalein dyes in having such a rigid tricyclic structure that two monobromo, four dibromo, and two tribromofluoresceins are possible. A study of the kinetics of formation of these isomers might be of help in the elucidation of the stereochemistry of the bromination reaction. This stepwise biological bromination by the dogfish may be analogous to the biogenesis of thyroxine where tyrosine residues undergo iodination[7].

ANATOMY

Electron Microscopic Identification of Autonomic Nerve Endings

THE endings of some autonomic axons, which are presumed to be either adrenergic or cholinergic in function, can be distinguished using the electron microscope by their different populations of vesicles. This was first pointed out by de Robertis and Pellegrino de Iraldi[1]. The cholinergic fibres, as in motor end-plates of skeletal muscle, contain uniform vesicles consisting of an outer wall of unit membrane enclosing a central core which is scarcely denser than the adjacent cytoplasm. In contrast, adrenergic fibres contain similar vesicles, but mixed with a minority possessing an electron-dense central core or granule. The first type are conveniently called agranular vesicles, and the second type granular, or dense cored, vesicles. However, some doubt has been cast on the reliability of granular vesicles as an index of adrenergic function. Whereas in the osmium tetroxide-fixed rabbit iris[2] they are present abundantly in the axons supplying the dilator muscle, they are not present at all, or only very rarely in the rodent iris with similar fixation[3,4]. They appear to be absent also in axons supplying the outer longitudinal muscle coat of the guinea-pig vas deferens[5], though they are invariably present in the circular muscle coat of many species including the guinea-pig. Isolation of granular vesicles in homogenates by differential centrifugation in sucrose gradients has proved difficult. They are seldom seen in heart homogenates, for instance, even in fractions known to contain a high concentration of norepinephrine[6], but do appear in certain fractions of homogenized hypothalamus[7]. The possibility has been raised that the granules within the granular vesicles are artefacts unworthy of serious consideration. On the other hand they may represent in miniature the large granules of adrenal medullary cells which contain high concentrations of bound catecholamine. Assuming that this is so, care must be taken in fixing tissues containing adrenergic axons to avoid severe losses of catecholamines by diffusion or extraction.

We have looked for adequate methods of fixing the iris, and have found that ice-cold 3 per cent potassium permanganate in 0·1 M phosphate buffer at *p*H 7·0, in contrast to buffered osmium tetroxide or glutaraldehyde solutions, is much more reliable for preserving granular vesicles, though the over-all quality of fixation may be somewhat inferior. With this fixative, the granular vesicles can be constantly demonstrated in the rat and mouse iris in their expected situations. The same is true for the longitudinal muscle of the guinea-pig vas deferens. Indeed it is likely that wherever autonomic axons show a specific fluorescence with the Falck and Hillarp technique they will be found electronmicroscopically to contain granular vesicles after permanganate fixation. It is interesting that while permanganate has little or no merit as a histochemical reagent for catecholamines, fixatives combining glutaraldehyde and dichromate, buffered to *p*H 6·5, for which histochemical merit is claimed[8,9], appear to wash out the catecholamines from very thin tissues like rat iris and thus fail to preserve the granular vesicles. It should be mentioned that the permanganate solution, though grossly hypertonic, does not shrink tissues unduly and the swelling of mitochondria, which is a well-known feature of the weaker solution proposed by Luft[10], is minimized but not abolished. Whether permanganate would also be the fixative of choice for pellets of homogenized tissue remains to be determined. As there may be loss of catecholamines from vesicles occurring during the various manipulations in sucrose gradients, before the fixative is applied to the centrifuged pellet, a positive result with permanganate can hardly be predicted. A further interesting possibility is that, even in cases where osmium tetroxide fixation is successful in preserving granules in some vesicles, we may not be visualizing anything like the full catecholamine content of an axon, but merely the part which is not washed out. This may be one reason why agranular vesicles are so numerous in adrenergic nerve endings.

Mast Cells in the Central Nervous System

IN the central nervous system, the occurrence of mast cells in the pineal[1] and neurohypophysis[2] appears to be well established. They have been noted in the normal olfactory bulb[3]. They occur also in the human brain under pathological conditions, for example around infarcts and in the plaques of multiple sclerosis[4], as well as around the cerebral vessels of ageing animals[5].

We have recently examined the brains of ten hedgehogs (*Erinaceus europaeus*) in coronal, horizontal and

sagittal sections, and found cells apparently identical with mast cells which are localized to the diencephalon. These cells were observed only in the thalamus, epithalamus and metathalamus, and were located predominantly in the nucleus dorsomedialis thalami. We have not been able to confirm the previous report of the presence of mast cells in the olfactory bulb.

The basophilic cytoplasmic granules of these cells (Fig. 1) are so numerous that the nuclei are often hidden as in the mast cells of connective tissues. The cells are histochemically identical with the mast cells found in the tongue of the same species, in so far as their granules stain strongly with alcian blue, metachromatically with thionine (Fig. 2), contain peroxidase and are periodic acid-Schiff-positive and slightly sudanophilic.

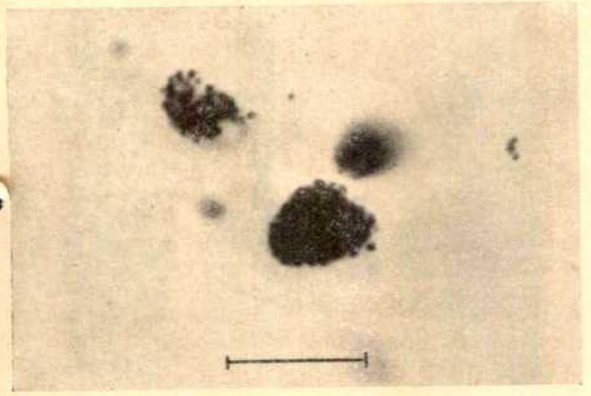

Fig. 1. Mast cells in the thalamus of the hedgehog showing basophilic cytoplasmic granules. Giemsa stain. Scale, 10μ

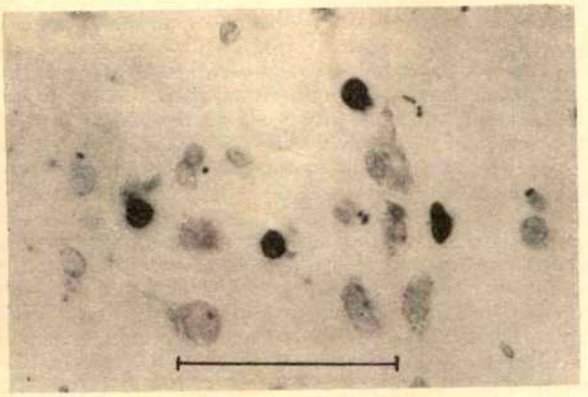

Fig. 2. Metachromatic staining of four mast cells in the nucleus dorsomedialis thalami. Schmorl's thionine technique. Scale, 50μ

Further investigations of other Insectivora and hibernating animals should reveal any physiological or taxonomic correlates of the presence of mast cells in the diencephalon. The possibility of intra-thalamic release of heparin, histamine or serotonin is of considerable interest in relation to local haemodynamic changes during hibernation.

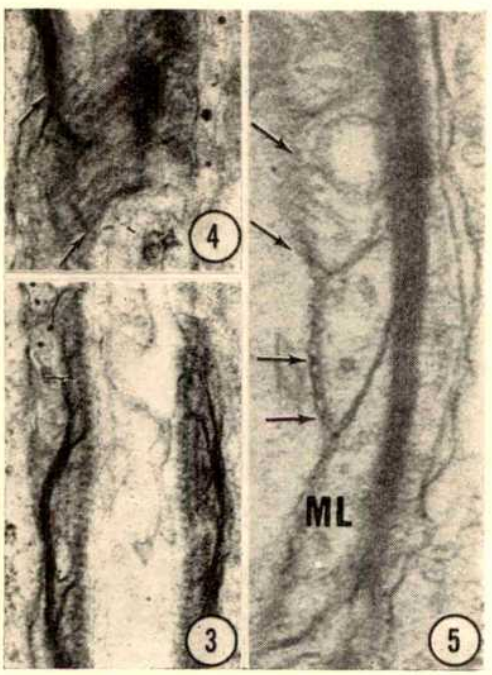
A Structural Specialization at Nodes of Ranvier in the Central Nervous System

DURING the course of an electron microscopic study of the hippocampal region in the rat an interesting periodicity associated with the axolemma was observed in the area of termination of the myelin sheaths either at nodes of Ranvier or at the last myelinated segment of an axon. As this would seem to be a constant feature of myelinated axons, not only in the hippocampus and dentate gyrus which we have investigated most intensively, but also in other sites that we have examined, and because it does not appear to have been described elsewhere, a brief account of our findings will be presented.

The material on which these observations are based was derived from the brains of adult rats perfused under hypothermia with 3 per cent glutaraldehyde in 0·1 M sodium phosphate buffer with added calcium chloride. Small blocks of tissue were post-fixed in 2 per cent osmium tetroxide, embedded in 'Araldite' and the sections stained with lead citrate.

In longitudinal sections through the nodal region where the myelin lamellae unfold to form the characteristic loops of glial cytoplasm, a striking periodic density is seen along the outer surface of the axolemma and extending into the cleft between this membrane and that of the myelin loops (Figs. 1–3). These regular densities which are between 100 Å and 150 Å wide, repeat with a periodicity of 300–400 Å and extend over nearly the whole area of 'peeling off' of the myelin lamellae. Between six and eighteen densities may underlie a single loop—the number depending solely on the length of the individual loops. While the densities always cease abruptly at the beginning of the unmyelinated segment of the axon, they may extend for a variable distance along the first cytoplasmic loop which is formed by the innermost myelin lamella. As a rule, the only point at which the regularity of the densities is interrupted is opposite the cleft between adjoining myelin loops (Fig. 2). Oblique or tangential sections through the nodal region (Figs. 4 and 5) show a characteristic cross-striation which suggests that the



Figs. 1 and 2. Longitudinal section through part of a node of Ranvier to show the periodic densities over the region of the myelin loops (*ML*). The arrows indicate the area which is enlarged in Fig. 2. The axon gives off a collateral branch (*C*) and the arrow heads indicate a continuation of the periodic thickenings on to the proximal part of the collateral. (Fig. 1, × *c.* 41,600; Fig. 2, × *c.* 145,800)

densities either encircle or, possibly, spiral around the axon. In one instance a continuation of the periodicity has been observed in relation to a myelin loop which is wedged in the angle between an axon and a collateral branch (Fig. 1). The precise localization of the densities is rather difficult to determine; but, judging from the slight indentations which occur along the inner surface of the axolemma opposite the periodic densities, it would appear that the densities are mainly a specialization of the axolemma. Certainly, they seem to be more closely associated with this membrane than with the membrane of the myelin loops. In Fig. 6 we have attempted to reconstruct these membrane relationships as they appear in the paranodal or terminal region of a myelinated fibre to illustrate the form and position of these periodic densities.

It is difficult to account for the failure of earlier workers to recognize this very striking specialization of the nodal region, unless perhaps it is a feature which is only clearly revealed by aldehyde fixation and/or lead staining. It is not uncommon for different fixatives to give rise to variations in the appearance of structures under the electron microscope and it is conceivable that this may be the case here. But, whatever the reason may be, it is clear that some component of the related axolemma and myelin loops may appear as a series of annular or spiral densities around the nodal or terminal region of myelinated axons in the central nervous system.

Robertson[1] has described a 'fusion' or 'tight junction' between the axolemma and the membrane of the myelin loops at nodes of Ranvier in permanganate-fixed sciatic nerves of frogs and has illustrated this diagrammatically as a continuous density extending over the whole length of each myelin loop. A re-examination of the published micrographs, however, suggests that what has been interpreted as a continuous density may in fact be periodic.

In a recent investigation of the desmosome-like thickenings which occur between adjacent Schwann cell membranes in peripheral nerves, Harkin[2] has published micrographs of nodes of Ranvier in rat sciatic nerves from glutaraldehyde-fixed and lead-stained material. In one

Figs. 3 and 4. Two parts of a section through the same node to show the appearance of the periodic densities where the axon is sectioned slightly obliquely (Fig. 3) and tangentially (Fig. 4). (× *c.* 54,100)

Fig. 5. Part of an obliquely transverse section through the paranodal region of another fibre. Arrows indicate the orientation of the membrane densities related to the myelin loops (*ML*). (× *c.* 83,300)

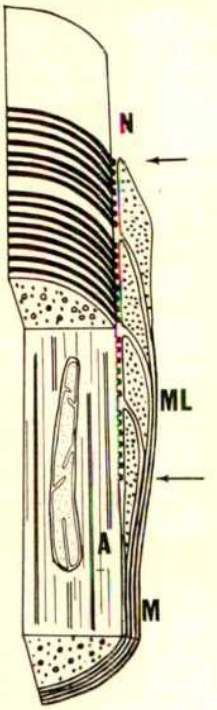


Fig. 6. A schematic representation of the axolemmal thickenings in the region of a node of Ranvier. *N*, Nodal region; *ML*, myelin loops; *M*, myelin lamellae; *A*, axon

of these the same type of periodicity as we have found is clearly seen between some of the myelin loops and the axolemma (especially over the loops labelled 1 and 2 in his Fig. 1), but unfortunately no reference is made to this in either the text or legends. In view of this, it seems likely that periodic densities associated with the axolemma are a common feature of both central and peripheral nodes and it is reasonable to suppose that their structural and functional significance will prove to be the same in the two situations.

At least two possibilities may be entertained as to the significance of these densities in the nodal and terminal regions of myelinated axons. The first is that they may provide a tight attachment for the myelin loops which would 'anchor' them to the axolemma. Quite apart from lending mechanical stability to the unfolded myelin lamellae, such an arrangement would also act as a physical barrier between the periaxonal space around the node on one hand, and the narrow cleft between the myelin lamellae and the axon on the other[3]. In support of this suggestion is the finding that the periodic densities are limited to the region of unfolding of the myelin lamellae. The fact that they usually end about half-way along the first or innermost loop may also be taken as support for the view that the separation of the myelin lamellae to form loops is the critical factor which leads to the appearance of the regular densities along the axolemma. The second possibility is that this structural specialization is in some way involved with the mechanism of saltatory conduction, possibly by concentrating current flow at the nodal segment of the axon.

This work was supported in part by grants from the U.S. Public Health Service.

ENTOMOLOGY

'Catalysomes', or Enzyme Caps on Lipid Droplets: an Intracellular Organelle

WHILE studying the distribution of acetylcholine and other esterases in the insect *Rhodnius*[1], it was observed that every droplet of triglyceride in the cells of the fat body has a small disk-like area or 'cap', 1μ or less in diameter, which is the site of an enzyme that will hydrolyse 5-bromoindoxyl acetate (method of Holt[2]) and naphthol AS acetate (method of Pearse[3]). This esterase is not inhibited by eserine or other inhibitors of the cholinesterase group; it was believed to be a lipase and it was concluded that the active disk or cap constitutes an organelle responsible for the liberation and perhaps the uptake of fatty acids in the droplets of stored lipid[1].

More recently it has been shown by Chino and Gilbert[4] that fatty acids in insects are transported in the form of diglycerides incorporated into lipoprotein; and that liberation of the stored lipid is an energy-demanding process which involves the simultaneous oxidation of carbohydrate[5].

In the course of an investigation of the histology and histochemistry of the fat body in *Rhodnius*, which is now being written up for publication, it was observed that nicotinamide–adenine dinucleotide diaphorase ($NADH_2$ as substrate, with nitro-BT as tetrazolium compound[6]), besides its expected localization in the mitochondria, is intensely active in the lipase-containing caps on the droplets of fat (Fig. 1, *a*). In the absence of added substrate endogenous activity gives a barely detectable reaction. Of the enzymes investigated so far, the 'caps' contain also the dehydrogenases of isocitrate (+nicotinamide adenine dinucleotide phosphate, NADP, as co-enzyme), α-ketoglutarate (+NAD), succinate (without added co-enzyme), malate (+NAD), glutamate (+NAD), β-hydroxybutyrate (+NAD) and a very weak lactate. The dehydrogenases of the pentose cycle acting on glucose-6-phosphate and 6-phosphogluconate (+NADP) are virtually absent. In the G-'Nadi' reaction indophenol blue is sharply localized in the muscle mitochondria[7]. In the fat body cells the dye rapidly accumulates in solution in the droplets of lipid, but the site of its formation cannot be localized.

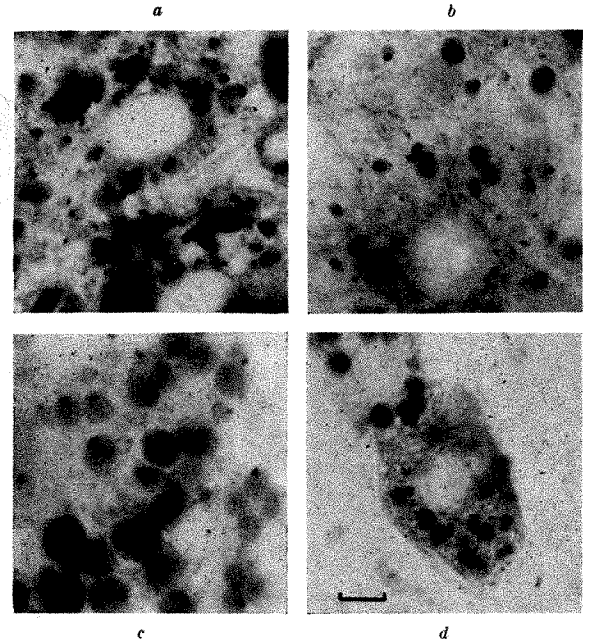

Fig. 1. Whole cells containing lipid droplets. Fixation: glutaraldehyde at *p*H 7·4. Fat staining: sudan 4. Light filter: greenish yellow. Scale (shown in *d*) equals 5μ. *a*, Fat body cells of *Rhodnius*: NAD-diaphorase. Mitochondria around nuclei, catalysomes on lipid droplets. *b*, The same, showing some catalysomes with invisibly small lipid droplets among the mitochondria. *c*, Fat cells in mesentery of mouse: 5-bromoindoxyl acetate method for esterase. Catalysomes in focus on many of the fat drops. *d*, The same: NAD-diaphorase. Mitochondria and lipid droplets with catalysomes

It appears likely, therefore, that these enzyme sites contain all the enzymes of the Krebs cycle and presumably the cytochromes. They are probably responsible for the synthesis of stored lipid (which is readily formed in the fat body cells from sugars and amino-acids[8]) as well as for its preparation for distribution in the circulating blood.

For convenience these organelles, which may be appropriately termed 'catalysomes', have been chiefly studied in the fat body of *Rhodnius*. But their presence is readily confirmed in the developing fat cells in the mesentery of the young mouse. Here they have the same appearance and contain both esterase and NAD-diaphorase (Fig. 1, *c* and *d*). In both insect and mammal they arise as intensely reactive granules in the cytoplasm between the mitochondria (Fig. 1, *b*). A minute droplet of lipid then appears in contact with the granule and as this droplet enlarges the granule becomes a crescent and finally a sharply localized and slightly raised spot on the surface of the oil drop. The fine structure of this organelle is being studied in collaboration by A. V. Grimstone.

Catalysomes must often have been seen before, but apart from their esterase activity[1], their significant association with lipid droplets has not been recognized. It was reported by Chino[9] that much of the cytochrome oxidase in the developing egg of the silkworm was contained in particles that were carried up with the lipid layer during the centrifugation of homogenates. These particles were probably catalysomes.

Pertinacity of Host-seeking Behaviour of *Aedes aegypti*

MOSQUITOES on the hunt are persistent pests. To the best of our knowledge, this persistence has not been quantitated. Use of mosquitoes in lengthy biting or probing experiments requires that the drive to bite or probe does not fatigue during the minutes or hours of the experiment, so that the experimental variable can be reliably quantified. The following observations were made to record the pertinacity (and lack of fatigue) of *Aedes aegypti* females.

Adult female *Aedes aegypti*, var. *queenslandensis*, were reared in cages, 1 ft.^{3}, in the presence of males. They were fed 5 per cent sucrose solution until the experiment began. 5–9-day-old females were placed in small cages, 5 × 5 × 1·5 cm, made of a wire frame and covered with nylon net. In probing experiments these cages were suspended 1 cm above the inner surface of the forearm of a volunteer. The mosquitoes were observed and any attempts to probe were recorded.

Five mosquitoes in a small cage were observed for 30 min. The number probing towards the arm was recorded continuously. Ten replicates, using different mosquitoes but the same subject, were performed.

The 30-min experimental period was divided into three successive 10-min periods for purposes of comparison.

Table 1. PROBING ACTIVITY OF FIVE *Aedes aegypti* FEMALES OVER A HUMAN FOREARM IN A 30-MIN PERIOD*

	0–10 min	11–20 min	21–30 min
Percentage of time probed	87·78 ± 4·3	85·99 ± 6·4	84·5 ± 8·0
Percentage of mosquitoes which had probed	42·4 ± 4·7	45·2 ± 8·6	46·1 ± 6·7

* Each figure is a mean of ten replicates ± *S.E.*

Table 2. PROBING ACTIVITY OF A POPULATION OF *Aedes aegypti* FEMALES OVER A HUMAN FOREARM

Trial No.	Seconds to 50 per cent probing*
1	24·2
2	24·1
3	20·3
4	23·6
5	15·4
6	24·9
7	22·1
8	21·2
9	22·5
10	22·3

* Each figure is a mean of ten replicates.

Two values were determined for each 10-min period: (1) '*T*', the percentage of time one or more mosquitoes were probing, and (2) '*P*', the percentage of probing activity (100 per cent being five mosquitoes probing without interruption for 10 min).

As can be seen from Table 1, mosquitoes probed during 86·0 per cent of the available time, and during this time an average of 44·5 per cent of the mosquitoes probed. No significant difference of activity was seen when the three successive 10-min periods were compared.

We felt that a population study as mentioned here might mask activity cycles of individual mosquitoes. The experiment was therefore repeated twice with one female per cage. Probing activity was recorded continuously for 30 min. The pattern of 'probing' and 'not-probing' was completely random, as can be seen from Fig. 1. The shortest probing period was 1 sec, the longest 184 sec. Probing periods tended to be about 8–10 sec, and inactivity periods about 5–7 sec. When analysed by three successive 10-min periods no significant difference of probing activity was demonstrated.

It was planned to use the time to initiation of probing as a measure of attractiveness of human subjects, and it was presumed that a shorter initiation time indicated a more attractive subject. The variability of this initiation time with repetition and passage of time was the subject of this experiment. Ten female *A. aegypti* were placed in a small cage. The time from first exposure to the forearm to the time when at least five were probing simultaneously was measured. When five mosquitoes were probing together the arm was withdrawn from beneath the cage, the mosquitoes allowed to rest for 1 min, and then the arm replaced below the cage. One hundred successive determinations, over a 2·5-h period, were performed, using the same arm and the same mosquitoes. The results are recorded in Table 2, grouped in ten trials of ten successive determinations each. Obviously, no diminution of vigour occurred with repetition of exposure.

It was desired to know whether continuous exposure to the immediate presence of the host would lead to sensory adaptation and diminution of probing and biting. A small cage containing five female *A. aegypti* was fastened to the forearm of an experimenter, but spaced 1 cm from the skin by a rubber ring. The experimenter carried on his normal indoor activities during the 12 h of the experiment, covering the cage with his shirt sleeve. At intervals he would observe the mosquitoes for probing, and at the end of the 12 h the spacer ring was removed and the cage placed directly on the skin. Three replicates were carried out. No attempt was made to quantitate probing behaviour, but on all occasions that they were observed, probing activity was obvious. At the end of 12 h all subjects were bitten by all their mosquitoes.

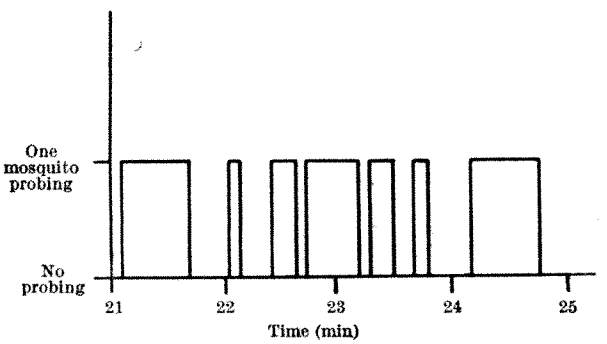

Fig. 1. The pattern of 'probing' and 'not-probing'

These experiments give indication of the untiring host-seeking behaviour of *A. aegypti*. Neither perception of the host, initiation of probing, continuation of probing, nor biting urge seemed to diminish with repeated or continued exposure to the host. The observations confirm casual ones made on free-flying mosquitoes, and also now make it possible to undertake repetitive or continued use of mosquitoes in the laboratory without fear of diminished vigour.

This investigation was supported by the U.S. Army Medical Research and Development Command, Department of the Army.

MICROBIOLOGY

Location of Spore and Vegetative Antigens of *Bacillus cereus* by means of Ferritin-labelled Antibodies

FERRITIN labelling of antibodies[1] provides a method for the study of antigen/antibody reactions at the subcellular level using the electron microscope. This technique has now been successfully applied to numerous problems in bacteriology, virology and pathology[2].

Antigenic changes occurring on the surface of *Clostridium sporogenes* and *Bacillus cereus* during germination and sporulation have been investigated using fluorescent labelled antibodies[3,4]. Similar labelling of these antisera with ferritin should enable antigenic changes not only on the surface, but also within the organisms to be followed. Two approaches to this problem, namely, pre-embedding and post-embedding staining with ferritin labelled antibodies, are possible[5]. Some preliminary observations on the pre-embedding staining of spores and vegetative cells with appropriate ferritin-labelled antibodies are described here.

Antisera prepared against the spores and vegetative cells of *B. cereus*, var. 'Terminalis'[4], were coupled with ferritin using toluene 2 : 4-di-isocyanate as coupling agent[6]. 0·2 ml. amounts of a concentrated suspension of spores and vegetative cells, previously fixed for 18 h in 10 per cent phosphate buffered formalin, *p*H 7·2, were mixed with 0·1 ml. amounts of the appropriate ferritin-labelled antibody and shaken at 37° C for 0·5 h. After centrifuging the deposits were washed six times in 10 per cent phosphate buffered formol saline, *p*H 7·2, and processed for electron microscopy. The specimens were post-fixed in osmic acid and embedded in 'Maraglass'[7]. Sections were cut on an L.K.B. ultratome, using glass knives, and collected on 200 mesh carbon coated grids. They were examined in a Philips *EM* 200 electron microscope at 60 kV.

Specific staining of the appropriate antigens was observed by both spore and vegetative ferritin-labelled antibodies. In Fig. 1 it can be seen that the ferritin-

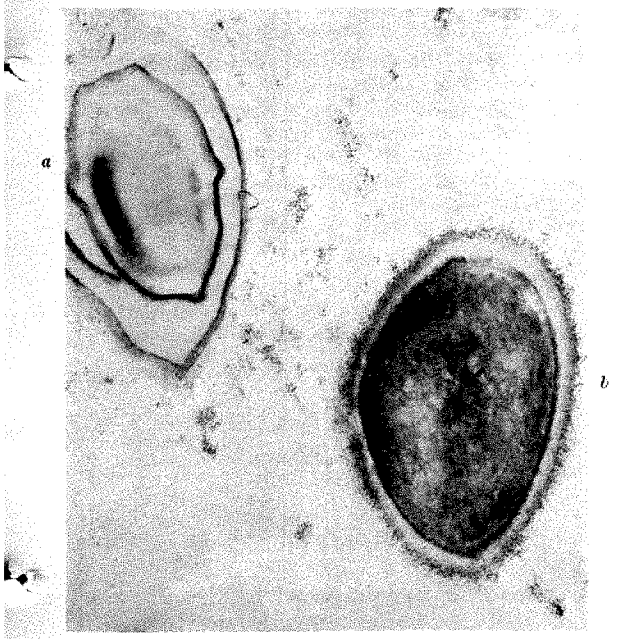

Fig. 1. Electron micrograph showing (*a*) spore and (*b*) vegetative cell of *B. cereus* var. 'Terminalis' stained with vegetative ferritin-labelled antibodies

labelled vegetative antibody is specifically located around the vegetative cell only. The background always contained a small number of ferritin particles, which presumably became detached during processing, but these did not interfere with the interpretation of the photographs.

Further intracellular location of vegetative antigens in spores has been achieved by similarly staining disintegrated spores. This will be the subject of further communications.

Amino-acid Protection of Ultra-violet-irradiated *Bacillus subtilis*

IT has been reported[1] that cultivation of *Hansenula wingei*, prior to ultra-violet irradiation, in beef-extract glucose broth supplemented with small concentrations of either tryptophan, cystine, tyrosine, phenylalanine, leucine, cysteine, threonine, isoleucine, histidine, or the amino-acid analogues, ethionine or norvaline, protected this yeast against ultra-violet exposure. The hypothesis was made that amino-acids may be strongly active as protective or reactivating agents in Gram-positive organisms, but only slightly active in this capacity in Gram-negative organisms because of permeability differences in the two types of organisms. The present investigation was initiated to determine if amino-acids reverse or protect against the inactivating effects of ultra-violet radiation in a Gram-positive bacterium.

For experimental purposes, *Bacillus subtilis ATCC* 6051 cells were grown overnight at 37° C in shaken 125 ml. flasks of a defined broth medium containing 0·2 per cent glucose; 0·8 per cent L-glutamic acid; 10 ml. of an aqueous salt solution composed of 0·2 per cent magnesium sulphate H_2O, 0·05 per cent calcium chloride, 0·05 per cent sodium chloride and 0·0001 per cent copper sulphate; 1 ml. of an aqueous salt solution containing 0·1 per cent manganese sulphate and 0·1 per cent iron sulphate; plus 0·05 per cent of either L-phenylalanine, L-glycine, L-proline, L-tyrosine, L-serine, L-tryptophan, L-alanine, L-threonine, L-histidine, or L-methionine (Nutritional Biochemical Corporation, Cleveland, Ohio). The medium was phosphate buffered (0·15 M, *p*H 6·2 or 7·4 depending on the experimental design).

The cells from the respective cultures, including a non-enriched control culture, were collected and washed by centrifugation in sterile 0·85 per cent sodium chloride and used to prepare saline suspensions containing approximately $1·0 \times 10^6$ viable cells/ml. A 20 ml. volume of each suspension was transferred to sterile 90 × 15 mm Petri dishes; these plates (with covers removed) were placed 30 cm from a 12 in. ultra-violet lamp (A. H. Thomas Company, Philadelphia, Pennsylvania) which emitted light with a principal wave-length of 254 mμ and an intensity of 17 mW/cm² at 1 m. One ml. aliquots were removed from each suspension prior to ultra-violet treatment and after 2 and 4 min of irradiation. During the exposure period, the dishes were manually agitated. The aliquots, withdrawn at the respective intervals, were suitably diluted and plated with trypticase soy agar to allow the surviving cells to form colonies. Irradiating, sampling, diluting, and plating procedures were carried out in a dark room illuminated with a 25-watt, red photographic bulb (Westinghouse Corporation, Bloomfield, New Jersey). Recovery plates were placed in closed boxes and incubated at 37° C for approximately 36 h. The protection afforded by the amino-acids against ultra-violet inactivation was determined by counting the colonies arising on the recovery plates and calculating the percentage of survivors after 2 and 4 min of ultra-violet exposure.

A typical experiment, which could be reproduced at will, is shown graphically in Fig. 1. It is noted that

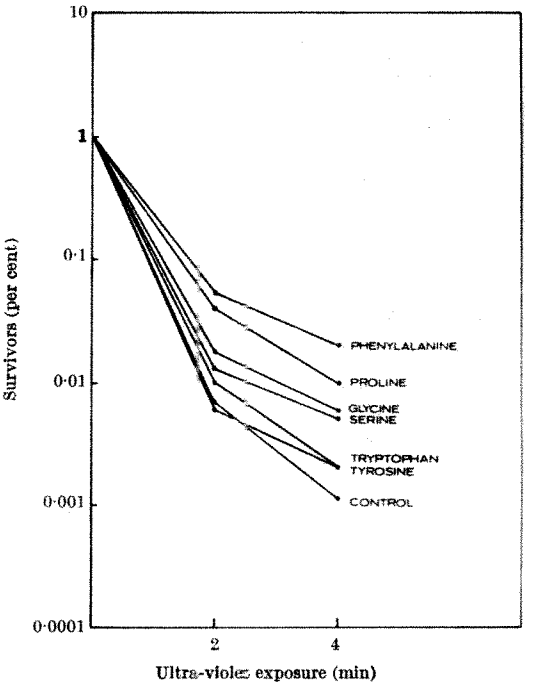

Fig. 1. Protection afforded by amino-acids (in an acid medium) against ultra-violet inactivation as shown by the percentage of cells surviving the indicated periods of radiation exposure. Prior to irradiation, all cells (except those of the control) had been grown in a defined phosphate buffered medium (0·15 M, *p*H 6·2) supplemented with 0·05 per cent of the indicated amino-acids

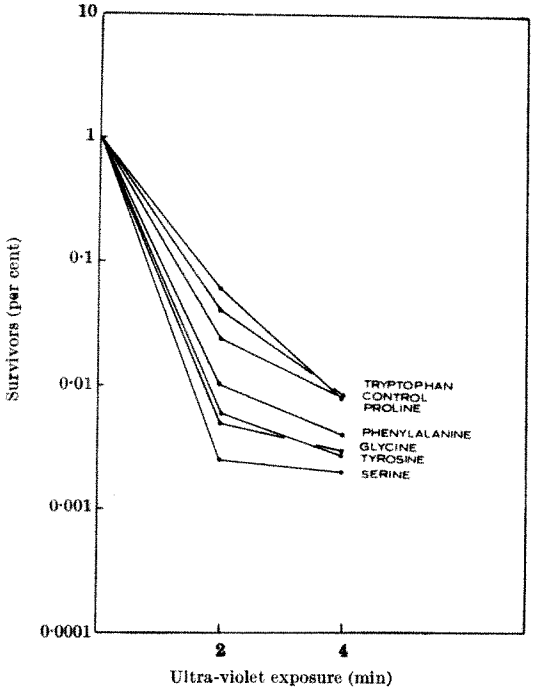

Fig. 2. Protection afforded by amino-acids (in an alkaline medium) against ultra-violet inactivation as shown by the percentage of cells surviving the indicated periods of radiation exposure. Prior to irradiation, all cells (except those of the control) had been grown in a defined phosphate buffered medium (0·15 M, *p*H 7·4) supplemented with 0·05 per cent of the indicated amino-acids

cultivation of *B. subtilis* in a defined acidic broth medium supplemented with phenylalanine, proline, glycine, or serine markedly increased the resistance of this organism against inactivating ultra-violet exposure. Tryptophan and tyrosine are less active in this capacity. Valine, methionine, and threonine (not plotted) yielded patterns of protection quite similar to phenylalanine; histidine closely paralleled proline. Fig. 2 shows the results obtained in a similar experiment in which the test organism was cultivated in an amino-acid enriched alkaline medium. Under these conditions, all the amino-acids, except tryptophan and proline, potentiated the lethal action of ultra-violet radiation. These seemingly contradictory results can be resolved in the following way: The *p*H of the acidic *B. subtilis* cultures was 6·2 which approximates the isoelectric points of phenylalanine, glycine, serine, tryptophan, proline, tyrosine, valine, and alanine[2]. As inner salts (zwitter ions) these compounds probably pass freely into *B. subtilis* cells; however, at *p*H 7·4, these amino-acids shift to their ionic form to which the cell boundaries of this organism may be relatively impermeable. This does not explain why most of the amino-acids, in an alkaline medium, increase ultra-violet sensitivity unless their presence in ionic form causes leakage of intracellular metabolites, perhaps analogous to that of surface active ionic compounds which bring about the release of purines and pyrimidines[3]. The loss of such compounds would be expected to increase ultra-violet sensitivity.

The possibility was considered that increased ultra-violet resistance in the amino-acid enriched cultures at *p*H 6·2 was partially or wholly attributable to increased sporulation. However, this explanation appeared invalid since the suspensions, which were later irradiated, were prepared directly from young rapidly growing cultures. Such cultures normally do not contain large numbers of spores[4]. In addition, microscopic examination of cells from the various cultures revealed that sporulation was negligible.

Although alanine is the only amino-acid reported to be a strong reactivator of ultra-violet irradiated *Escherichia coli*[5], the data presented here generally support the hypothesis that amino-acids may be strong reactivating or protective agents in Gram-positive organisms; however, this is equivocal until amino-acid protection against ultra-violet exposure has been demonstrated in a representative spectrum of Gram-positive organisms.

I thank Dr. R. F. Pittillo for his review of this paper and Mrs. Elwanda Johnson and Miss Carolyn Monerief for technical assistance.

GENETICS

Chromosome Breakage with Two Isomers of *l*-Threitol 1,4-*bis*methanesulphonate in Plants

THE chromosome breaking ability of *l*-threitol 1,4-*bis*-methanesulphonate was investigated in three plant species[1]. Chemical and cytological[2,3] evidence supports the fact that this compound can transform slowly *in vivo* into an active *bis*epoxide. The differential mutagenic activity of the *l*(+) and *d*(−) isomers of *bis*epoxybutane was investigated in *Penicillium multicolor* and in *Vicia faba*[4]. The *l* isomer exerted a higher activity.

This communication attempts to estimate the activity of two isomers of *l*-threitol 1,4-*bis*methanesulphonate: *d*-threitol 1,4-*bis*methanesulphonate and -erythritol 1,4-*bis*methanesulphonate. For this purpose, seeds of *Vicia faba* (ssp. *minor* var. Åkerböna Weibull) and *Nigella damascena* (variety Miss Jekyll) were treated with several concentrations of the compounds at 21° C. The possible influence of a 21-h pre-soaking time was investigated in *Vicia*.

In the first set of experiments, seeds were treated with solutions containing 40 mg of each chemical per 100 ml. distilled water for 3 h. After washing, they were allowed to germinate in Petri dishes. Root tips were fixed at different times corresponding to the first and second mitotic cycles. Successive fixations were necessary because the mitotic cycle was found to be delayed in the previous work[3].

The results of the first set of experiments in *Vicia* are summarized in Fig. 1. For the *l* configuration these results are in agreement with previous findings[1,3]. The activity of this compound is much higher than in the case of the two other isomers.

The differences further increase for the second fixation time which corresponds principally to the second mitotic cycle.

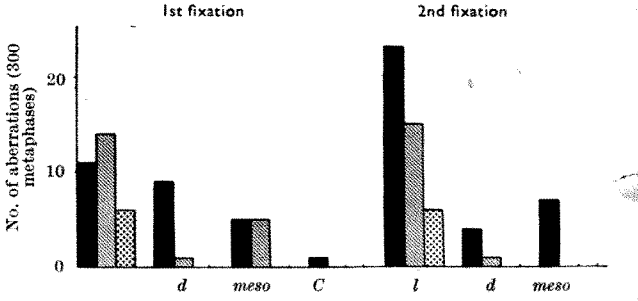

Fig. 1. *Vicia faba:* dry seed treatments. Effects of a dose (40 mg/100 ml./3 h) of the three isomers compared with control level (*C*). Black, one-hit aberrations; hatched, two-hit aberrations; dotted, minutes

No significant difference occurred between the efficiency of *d* and *meso* isomers, although the amounts of aberrations induced by these compounds were significantly higher than the control level.

A period of pre-soaking still increased the differences between the activity of the isomers, particularly for one-hit aberrations (Fig. 2). A delayed effect was observed with *l* isomer, whereas *d* and *meso* isomers seemed to exert their maximum activity during the first mitotic cycle.

In the second set of experiments, *d* and *meso* isomers were tested at very high concentrations in which the *l* isomer had a complete inhibiting effect after a few mitoses (Fig. 3). At such a high dose, the *l* configuration could not be tested on pre-soaked seeds owing to the immediate root degeneration.

Comparing these two experiments, no significant increase of the effect with the dose was found to occur (Fig. 3).

If we make a comparison with previous findings on the *l*-isomer[1,3] in which root tip fixations were carried out over a long period of time, it can be stated that the *d* and *meso* compounds are about 10–20-fold less efficient than the *l* compound. This difference is much greater than that between the *l*(+) and *d*(−) isomers of *bis*epoxybutane. In addition, some qualitative differences appeared. For example, minutes, that is chromosome fragments smaller than 1μ, were only observed with the *l* compound.

In the last set of experiments the results obtained in *Vicia* could be repeated in *Nigella* with *d* and *l* isomers (Fig. 4). For the *l* compound a proportionality between dose and amount of aberrations exists. The higher the dose, the greater the difference between the efficiency of both compounds. After a first fixation (46 h) no aberrations were observed.

On the basis of these data, it can be concluded that in some respects *d* and *meso* compounds behave as monofunctional alkylating agents, whereas the *l* compound has a difunctional action. Cytological arguments in favour of this are:

(i) The difference in activity at the chromosome level is the same as for other classes of alkylating agents, for example, between 'Myleran and ethyl methane sulphonate, and between *bis*epoxybutane (*meso* form) and ethylene oxide.

(ii) The delayed effect is much stronger for the *l* compound just as in the case of difunctional alkylating agents.

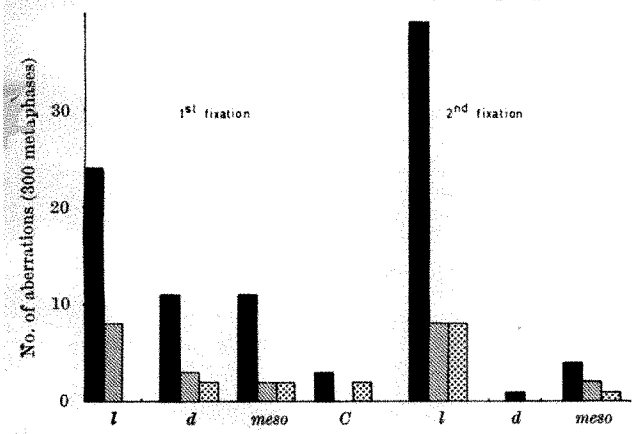

Fig. 2. *Vicia faba:* 21-h pre-soaked seed treatments. Key: same as for dry seeds

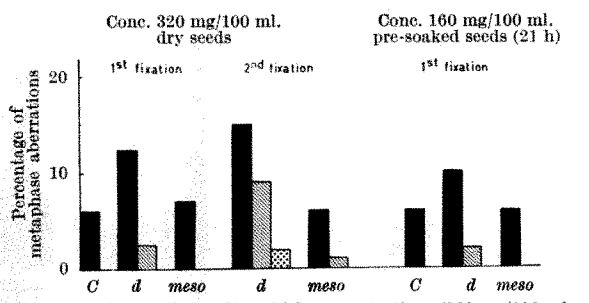

Fig. 3. *Vicia faba:* effects of two high concentrations (320 mg/100 ml. for dry seeds, 160 mg/100 ml. for pre-soaked seeds—100 metaphases analysed at each concentration)

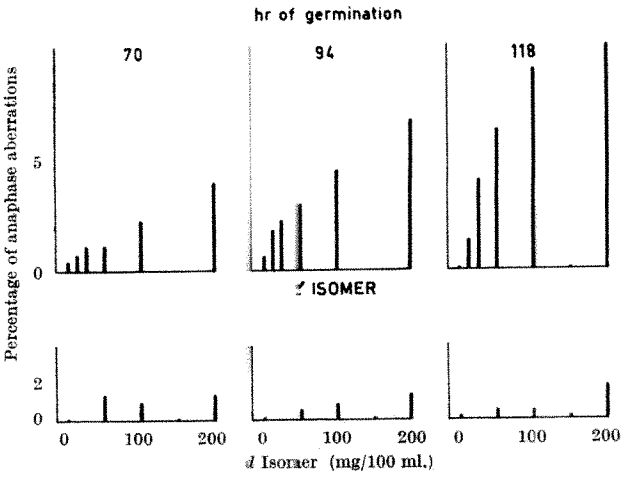

Fig. 4. *Nigella damascena:* dry seed treatments. Effects of increased concentrations of *l* and *d* isomers (300 anaphases analysed)

We thank Dr. W. Feit (Leo Pharmaceutical Products, Ballerup, Denmark) for providing the compounds.

SOIL SCIENCE

Effect of Iron on measuring Water Content with a Neutron Meter

THE neutron moisture meter is based on the principle that hydrogen atoms, having a mass almost the same as that of neutrons and much less than that of other atoms in such media as soils, are the only atoms which reduce the kinetic energy of neutrons from high to thermal levels by collision. It is assumed that all hydrogen atoms are chemically associated with oxygen atoms in the form of water and that the detected activity of slow neutrons is proportional to the moisture content of the medium. It is recognized that an error will result if an unknown quantity of hydrogen atoms is present in some other form.

It is also generally recognized by those familiar with these instruments that there are a number of elements that, when present in only small proportions, are capable of absorbing appreciable quantities of neutrons, thereby introducing errors into the relationship. With the exception of chlorine, which may also be present in the soil moisture in the form of salts, this effect is seldom considered in practice.

All elements are, in fact, capable of absorbing neutrons to a greater or lesser degree, but natural soils do not generally contain elements with high capture cross-sections. During calibration, the aggregate result of neutron absorption is included as a background effect; if use of the instrument is confined to the same soil type, or to another having the same absorption effect, no appreciable error is evident. If, on the other hand, an element with higher than average absorption is present

in the soil, the calibrated relationship may not be valid. Only three elements usually occurring in natural soils require special attention. They are iron (2·5 barns), potassium (2·2 barns) and titanium (5·2 barns). Of these, only iron and potassium normally occur in relatively large enough quantities. Both these elements were investigated to determine their effect on the results of moisture contents determined with a scintillation-type depth probe.

The first investigation was carried out using potassium carbonate solutions as a pilot experiment. The results showed a loss of detected thermal neutron activity roughly proportional to potassium concentration. In terms of weights, potassium at 2 per cent of the dry weight of the soil caused a reduction of 4 per cent in the counting rate.

The second experiment involving iron was conducted using a substitute soil medium of silica sand, activated bentonite, and water, to which quantities of ferric sulphate were added. The purpose of using such a mixture was to provide conditions similar to those existing in a natural soil in an attempt to explain an observed discrepancy between two calibration curves[1,2].

The important parameters are: bulk density, as this affects the normal scattering of neutrons in the medium; water content, which, when kept within the range experienced in the field, provides a normal flux of thermal neutrons in the medium; and a range of water : iron content ratios equivalent to that encountered in the natural soil so that the quantities of thermal neutrons available for capture by iron would be realistic.

In the proportions necessary to meet these requirements, the mixture had a consistency of soft mortar, and blending of the components was easily accomplished in a large pigment mixer. Because some of the water was in the form of water of crystallization, both moisture content and iron content were determined by chemical analyses. As expected, the moisture contents did vary over a narrow range, but it was possible to reduce the results to the basis of a uniform moisture content by referring to the initial calibration curve.

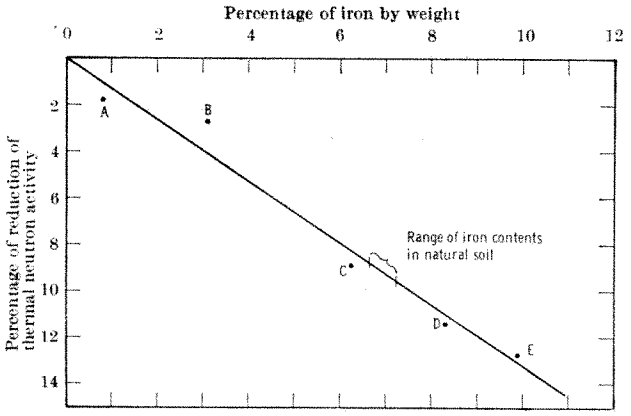

Fig. 1. Reduction of thermal neutron activity by iron absorption. Iron : water content ratios; *A*, 1·5 per cent; *B*, 6 per cent; *C*, 14 per cent; *D*, 20 per cent; *E*, 26 per cent

The results of five determinations of reduction of detected thermal neutron activity against iron content plotted in Fig. 1 show that the relationship is roughly linear. This appreciable reduction in counting rate goes far to explain the observed discrepancy. It is recommended that each calibration curve should be checked and, if necessary, adjusted for each soil type in which a neutron meter is used.

PSYCHOLOGY

Change in Transfer Function of Joint Receptor Output

HARRIS[1] and others[2,3] have suggested that a change in the 'felt position' of the arm might be involved in the adaptation of limb movements after exposure to visual displacement in a prism-wearing situation. Efstathiou and Held[4] have concluded that ". . . adaptation to displaced vision cannot be interpreted as a change in the felt position of the arm in relation to the body". The subject matter of their article is considered in a forthcoming article[5] and will not be dealt with here, but this communication bears on the conclusion quoted above.

The experiment reported here gives clear evidence that neither the 'felt position' hypothesis nor the more specific hypothesis of 'change in the transfer function of joint receptor output' can be dismissed.

The sub-system discussed here would appear to have two major components. The first is the motor outflow to the limb. It would seem reasonable to infer from Lashley[6] that this operates on a basis of dead reckoning. The second is position feedback, probably from receptors in the joints[7]. The former is the appropriate pattern of impulses to motor units in the limb, appropriate, that is, to the given visual (or other) position information. The latter is a mechanism which can record limb excursion independent of any load on the limb.

My hypothesis is that this highly simplified system will adjust to prismatic displacement in the following manner. As a result of the first attempt to point at a target while wearing prisms, the subject will see, *inter alia*, that he has to move his arm some distance farther or less far. However, his first attempt would have been successful in reaching the target if it had been in the position which the visual information would have led the subject to expect, taking into account the proprioceptive information about the initial position of the limb. Since the result was not a success, the subject will react by assuming that the position of the limb has been wrongly assessed; this results in a change in the setting of the transfer function relevant to the output of the joint proprioceptors.

The experiment consisted in the subject having the left arm supported horizontally and clamped in the sagittal plane. Three points were marked in a straight line down this arm, near the shoulder, elbow and wrist respectively. Immediately above the limb was a plate-glass sheet. The experimenter touched each of the aforementioned points with a glass rod five times at random. Each time the arm was touched, the subject indicated where this point was by placing the index finger of the right hand on the glass sheet.

The subject was then trained to point at visual targets wearing 20-dioptre prisms, and using only his left arm. During this training, knowledge of results was obtained after each movement and the head was restrained with a bite board. After ten successive pointings accurate to within ± 0·5°, the subject was again placed in the first situation, and asked to point at the adapted arm with the unadapted arm. Table 1 gives the results of these experiments.

Table 1. DIFFERENCE SCORES BETWEEN POINTINGS BEFORE AND AFTER ADAPTATION

		Point 1 (shoulder)	2 (elbow)	3 (wrist)
Mean in centimetres:	Subject (1)	−3·03	−3·8	−4·6
	Subject (2)	−0·93	−1·27	−2·87

Best fit straight line gives 6° adaptation for subject (1) and 4·5° for subject (2).

The form of the results should be that localizations successively further from the shoulder of the adapted arm have greater and greater linear error from the true arm position. Position receptors probably operate by signalling the angle which the segment takes up with respect to the

adjacent segment. Hence, if the transfer function alters, the locus of points which the subject behaviourally defines as corresponding to his left arm should be a straight line which deviates from the true position by 11°, with its origin at the shoulder. This assumes that there is full adaptation and no decrement of effect during the time spent collecting the results.

As can be seen, the results support this contention in so far as both subjects show a greater linear error from true arm position as the distance from the shoulder increases. Full angular adaptation is not shown, however, which shows the need for more rigorous treatment of the problem.

The most parsimonious explanation of this result is that it is based on a change in the transfer function of joint receptor output. To explain the result using the motor outflow component is difficult, bearing in mind that the immobile limb shows no on-going activity as recorded by electro myographic techniques[8]. Presumably, then, there is no motor-outflow which can be used to give the subject information about limb position in this situation.

Intermodal Transfer of Adaptation to Displacement

IT has been reported[1] that after adaptation of pointing behaviour in a prism-wearing situation, subjects will mislocate the position of an auditory stimulus if blindfolded and asked to point directly at it. The direction of this error of location is identical to that which would be expected if the subject were asked to point at a visual target after adaptation.

Before interpreting this result, it is necessary to know the generality of the phenomenon. If it could be shown that a subject exposed to a situation in which he received inaccurate auditory information as to the position of his pointing arm, then mislocated visual targets, there would then be strong evidence to suspect the implication of a change in the transfer function relating the output of joint receptors to some other component of the system, probably in the central nervous system, but as yet unspecified.

The experiment was carried out in three parts: (*a*) the subject pointed to visual targets without seeing his pointing limb at any time, and the investigator measured errors of location; (*b*) the subject pointed to a clicking auditory 'point-source' while blindfolded and with the pointing limb splinted. Pointing was carried out solely by horizontal abduction and adduction. Knowledge of success was given the subject when he depressed a switch which clicked a small loudspeaker which he thought was mounted directly above his pointing hand, but which in fact was offset by 12°. The task of the subject was to become as accurate as possible. After these adaptation trials, part (*c*), identical to (*a*), was carried out.

The results indicate that such auditory training leads to a change in pointing behaviour to visual targets at a level of confidence for t far in excess of 0·001.

It has been shown that there is no transfer of adaptation between limbs when the head is restrained[1]. The present cross-modal transfer of adaptation thus provides very strong evidence for change in transfer function for the output of the position receptors of the joints concerned. This is further confirmed in another article[2]. Alternative explanations could be put forward, but cannot satisfactorily explain how the subject could respond coherently if the joint was signalling information as to limb position which was incompatible with visually-derived information about the limb.

STATISTICS

Determination of the Solid Volume Percentage below Detectable Size in Coulter-counter Analysis

IN a recent paper Harris and Jowett[1] suggest an extrapolation technique for determining the solid volume percentage below detectable size in Coulter-counter analysis. The technique is based on the assumption that the Gates–Gaudin–Schuhmann or the Rosin–Rammler distribution is valid for the particles in question, and it is presupposed that, if a mathematical distribution function fits the experimental data, this function also holds for the undetectable part of the physical distribution.

From a logical point of view there is usually no strict connexion, if any relationship at all, between a physical particle-size distribution and the mathematical equation used to fit the physical data. Frequently the point is to find a curve, a graph of some suitable mathematical function, which runs through the experimental points with satisfactory precision. Often, however, it is rather difficult to obtain complete overlap, and in such cases the temptation to believe in the smoothed curve more than in the actual experimental points will always be present. Thus the application of mathematical distribution functions in order to estimate the fine end percentage of a measured particle-size distribution may introduce errors in the total volume. First, even if complete overlap is obtained, this does not prove that the mathematical function also holds for the undetectable part of the physical distribution. Secondly, if complete overlap is not obtained the evidence that an extrapolation of the mathematical function will coincide with the physical distribution is further decreased. These points have also been emphasized by Harris and Jowett[1].

In cases where the purpose of using the mathematical function is merely to estimate the total solid volume, I have found an alternative, 'non-mathematical', method very useful. The method will be illustrated using the data of Harris and Jowett[1]. The extrapolation has, of course, to be based on a more or less 'non-quantitative' valuation, but, as the following example shows, it is possible to obtain a visual impression of the plausibility of the extrapolation.

The primary data from the Coulter-counter give a cumulative number distribution over stated size, but this distribution may easily be recalculated to a volume or weight basis, as illustrated by the data of Harris and Jowett[1]. In Fig. 1 these data are plotted as a frequency histogram, instead of applying the commonly used integral (cumulative) form of the size distribution. If $\bar{v}_P$ is the mean particle volume in a narrow size class of Δn particles and Δx the size range of that class, the frequency is equal to $\frac{\Delta n \cdot \bar{v}_P}{\Delta x}$. The different frequencies are given in Table 1. Δv is here identical with the product $\Delta n \cdot \bar{v}_P$.

In fact, the histogram in Fig. 1 includes the whole experimental information available from the Coulter-counter analysis, and some extrapolation in the small particle range is necessary to obtain the total area under the frequency curve, which is a measure of the 100 per cent

reference. The area under the extrapolated part of the curve represents the unknown volume fraction below detectable size. In Fig. 1, two different extrapolations are suggested. The first one, which in simplified form is frequently used in our laboratory, for example in Coulter-counter analysis of cement, is given by the straight line between the central point, *a*, of the top of the finest histogram column, and the origin, *e*. The other is given by the 'best' straight line through the three finest histogram columns, a somewhat inaccurate formulation which allows different investigators to arrive at different results, although the differences would be rather small. In general, it is advisable to choose a standardized, well-defined extrapolation procedure to eliminate the individual variations among different investigators.

In Fig. 2, the cumulative volume percentages above stated size are plotted in a log-probability graph with three different 100 per cent references, one of them being identical with the result of Harris and Jowett and equal to 20,600. The other two are based on the above-described procedures, and the unknown percentages below detectable size are given by the areas of the triangles *ecb* and *dcb'* in Fig. 1.

Finally, attention is drawn to the dotted horizontal line through the point *f* on the ordinate axis in Fig. 1. This line represents the top of the histogram column from zero to 5·86μ based on the 100 per cent value 20,600 of Harris and Jowett. It seems to be reasonable to expect the decreasing pattern of the three finest histogram

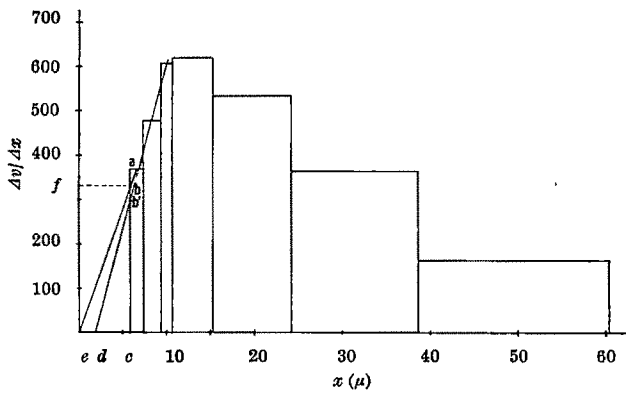

Fig. 1. Differential histogram of the Coulter-counter data of Harris and Jowett (ref. 1)

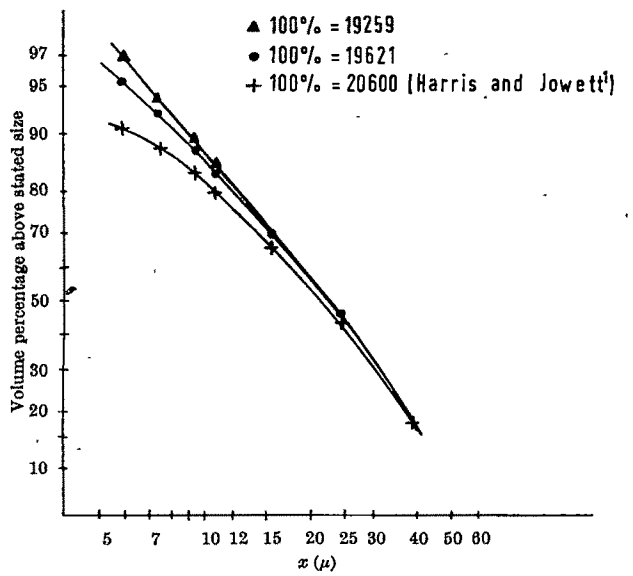

Fig. 2. Cumulative log-probability plots of volume percentage above stated size based on the data of Harris and Jowett (ref. 1)

Table 1. COULTER-COUNTER DATA OF HARRIS AND JOWETT (REF. 1)

x (μ)	Δx	Volume v above stated size (arbitrary units)	Δv	$\frac{\Delta v}{\Delta x}$	Volume percentage above stated size 100% = 20,600	100% = 19,621	100% = 19,259
60·40		0					
	21·72		3,528	162·4			
38·68		3,528			17·13	17·98	18·32
	14·49		5,264	363·3			
24·19		8,792			42 68	44·81	45·65
	8·91		4,731	531·6			
15·28		13,523			65·65	68·92	70·22
	4·60		2,842	617·8			
10·68		16,365			79·44	83·41	84·97
	1·35		818	605·9			
9·33		17,183			83·41	87·57	89·22
	1·93		920	476·7			
7·40		18,103			87·88	92·26	94·00
	1·54		566	367·5			
5 86		18,669			90·63	95·15	96·94
		Volume below detectable size:			1,931	952	590

columns to continue towards the origin in some way, and, if that is true, the 100 per cent value of Harris and Jowett is too large. I therefore suggest that a 100 per cent estimate of either 19,621 or 19,259 should be used instead of 20,600.

Distribution of the Derivative of the Likelihood Function

IT is common practice to approximate the distribution of the derivative of the log-likelihood, $\partial L/\partial\theta$, by a normal distribution with mean zero and variance $V = -[E(\partial^2 L/\partial\theta^2)]$. Calculations show that the three-moment χ^2-approximation:

$$(\partial L/\partial\theta) = a + b\chi^2_{(\nu)} \qquad (1)$$

can be a considerable improvement over the normal approximation, where a, b and ν (the degrees of freedom of the χ^2) are determined so that the right-hand side of (1) has its first three moments in common with $(\partial L/\partial\theta)$, that is:

$$b = \tfrac{1}{4}\mu_3/V,\ \nu = \tfrac{1}{2}V/b^2 \text{ and } a = -b\nu \qquad (2)$$

where $\mu_3 = 3(\partial V/\partial\theta) + 2E(\partial^3 L/\partial\theta^3)$.

Table 1. ERROR IN THE LIMITS OF θ: (APPROX. − TRUE)10^2

	Lower 0·01		Lower 0·05		Upper 0·05		Upper 0·01	
x	Normal	χ^2	Normal	χ^2	Normal	χ^2	Normal	χ^2
1	3	−1	2	0	54	6	150	21
2	13	−3	7	−3	45	4	136	17
3	20	−5	10	−2	47	4	128	14
5	30	−6	14	−2	43	4	119	10
10	41	−6	18	−2	39	3	107	8

To illustrate this, we consider a Poisson variate, x, with mean θ so that $\partial L/\partial\theta = (x - \theta)/\theta$. Substituting (2) in (1), we obtain in this case $\chi^2_{(\nu)} = 4(x + \theta)$ and $\nu = 8\theta$. Confidence limits for θ were obtained from Pearson and Hartley's[1] and Harter's[2] tables after introducing the usual continuity corrections, that is, using $x - \frac{1}{2}$ and $x + \frac{1}{2}$ when obtained the lower and upper limits for θ, respectively. The values are given in Table 1 and compared with the normal values. The true values are given by Bartlett[3]. For μ_3 small, that is, ν large, the square or cube root normal approximation of χ^2 can be used.

For several other applications of the χ^2-approximation (2), see Pearson[4] and Tiku[5–7].

Friday, May 20—Saturday, May 21

BIOCHEMICAL SOCIETY (at the School of Pharmacy, Brunswick Square, London, W C.1, and the Royal Free Hospital School of Medicine, Hunter Street, London, W.C.1)—460th Meeting which will include a Colloquium on The Contribution of Enzymes to the Structural Determination of Glycogen and Starch".

Saturday, May 21

NUTRITION SOCIETY (at the Sir John Atkins Laboratories, Queen Elizabeth College, Campden Hill Road, London, W.8), at 10 a.m.—Original Communications.

Monday, May 23

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS GROUP (at Savoy Place, London, W.C.2)—Colloquium on "A New Look at Energy Storage".

INSTITUTION OF ELECTRICAL ENGINEERS, ELECTRONICS GROUP (joint meeting with the I.E.R.E. Medical and Biological Group, at Savoy Place, London, W.C 2), at 10 a m. and 2.30 p m.—Discussion Meeting on "Electrical Aids to the Handicapped".

UNIVERSITY OF LONDON (in the Anatomy Theatre, University College, Gower Street, London, W.C 1), at 3 p m.—Prof. Raoul H. Bott (Harvard University). "The Riemann-Roch Question in Various Guises" (further lectures on May 24 and 26).*

ROYAL INSTITUTION, LIBRARY CIRCLE (at 21 Albemarle Street, London, W.1), at 5.30 p.m.—Mr. W. B. Proudfoot: "Copying Methods: Past and Present".

UNIVERSITY OF LONDON (at the Wright-Fleming Institute of Microbiology, St. Mary's Hospital Medical School, London, W.2), at 5.30 p.m.—Dr. C. E. G. Smith. "The Effects of Civilization on the Viral Zoonoses" (last of a series of four Almroth Wright Lectures) *

SOCIETY OF COSMETIC CHEMISTS OF GREAT BRITAIN (at the Washington Hotel, Curzon Street, London, W 1), at 7 p.m.—Annual General Meeting.

ROYAL GEOGRAPHICAL SOCIETY (at 1 Kensington Gore, London, S.W.7), at 8 15 p.m —Mr. G. de G. Sieveking. "In the Tracks of Early Man in Thailand".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

SENIOR LECTURER and a LECTURER/ASSISTANT LECTURER (with a good honours degree and industrial/research experience in any aspect of chemical engineering) IN THE DEPARTMENT OF CHEMICAL ENGINEERING—The Staff Officer, The University of Aston in Birmingham, Gosta Green, Birmingham, 4 (May 18).

PRINCIPAL LECTURER and a LECTURER IN THE DEPARTMENT OF PHYSICS to prepare students for honours degree of the University of London, and to assist with postgraduate courses and research—The Principal, West Ham College of Technology, Romford Road, Stratford, London, E 15, quoting Ref. RAW/JA/664/1 (May 20).

ASSISTANT LECTURER (preferably with an interest in some aspects of animal physiology) IN ZOOLOGY—The Registrar, The University, Manchester, 13, quoting Ref 109/66 (May 21).

RESEARCH OFFICER IN THE DEPARTMENT OF PHYSICS to undertake research on aspects of crystal growth—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (May 21).

ASSISTANT LECTURER IN SOCIAL ANTHROPOLOGY—The Secretary, The Queen's University, Belfast, Northern Ireland (May 23).

LECTURER OR ASSISTANT LECTURER IN BIOCHEMISTRY—The Registrar, The University, Leeds (May 23)

LECTURER OR ASSISTANT LECTURER IN SOCIOLOGY IN THE DEPARTMENT OF ADULT EDUCATION AND EXTRA-MURAL STUDIES—The Registrar, The University, Leeds, 2 (May 23)

LECTURER OR ASSISTANT LECTURER IN SOCIOLOGY—The Registrar, University of Kent at Canterbury, Canterbury, Kent (May 23).

LECTURER OR ASSISTANT LECTURER (preferably with an interest in the experimental psychology of perception) IN THE DEPARTMENT OF PSYCHOLOGY —The Registrar, The University, Leeds, 2 (May 23).

RESEARCH DEMONSTRATOR (with a good honours degree in psychology) IN PSYCHOLOGY—Prof. George Westby, Department of Psychology, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (May 23)

SECOND CHAIR OF ELECTRICAL ENGINEERING at Queen Mary College—The Academic Registrar, University of London, Senate House, London, W.C.1 (May 27).

ASSISTANT LECTURER OR DEMONSTRATOR (with medical qualifications registrable in the United Kingdom) IN ANATOMY—The Registrar, The University, Manchester, 13, quoting Ref 118/66 (May 28).

CHAIRS (2) OF PHILOSOPHY—The Assistant Registrar (Establishment), The University of Sussex, Stanmer House, Stanmer, Brighton, Sussex (May 28).

LECTURER IN THE DEPARTMENT OF MEDICAL PHYSICS to take charge of and pursue research in clinical physics work embracing radioisotopes and scanning, radiotherapy and radiodiagnosis—The Secretary, The University, Aberdeen (May 28)

LECTURER OR ASSISTANT LECTURER (preferably able to teach the theory of knowledge, logic or philosophy of science) IN PHILOSOPHY—The Registrar, University College of Wales, Aberystwyth (May 28)

ASSISTANT LECTURER OR LECTURER (with a special interest in X-ray diffraction) IN MINERALOGY—The Registrar, University College of Wales, Aberystwyth (May 31).

LECTURER IN ANATOMY—The Registrar and Secretary, The University, Bristol (May 31).

LECTURER IN PURE MATHEMATICS—The Secretary, The Queen's University, Belfast, Northern Ireland (May 31).

LECTURER (with a good honours degree in physics or mathematics, and some training and research experience, preferably experimental, in meteorology) IN THE DEPARTMENT OF METEOROLOGY—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (May 31).

ASSISTANT LECTURER IN THE DEPARTMENT OF METALLURGY OF THE FACULTY OF SCIENCE—The Registrar, The University, Manchester 13 (June 1).

ASSISTANT LIBRARIAN (with a good honours degree and preferably research experience and/or library qualifications) IN THE UNIVERSITY LIBRARY—The Registrar, The University, Manchester, 13, quoting Ref. 125/66 (June 3).

CHAIR OF ELECTRONIC COMPUTATION IN THE DEPARTMENT OF APPLIED MATHEMATICS—The Registrar, The University, Sheffield (June 4).

PROFESSOR, a SENIOR LECTURER and a LECTURER IN THE DEPARTMENT OF STATISTICS, University of Ibadan, Nigeria—The Inter-University Council, 33 Bedford Place, London, W C.1 (June 5)

RESEARCH ASSISTANT (preferably with interests in the field of fluid mechanics) IN APPLIED MATHEMATICS—The Registrar, University College of North Wales, Bangor, North Wales (June 6).

COURTAULDS CHAIR OF CHEMICAL ENGINEERING at Imperial College—The Academic Registrar, University of London, Senate House, London, W.C.1 (June 7).

SENIOR LECTURER or LECTURER (preferably with interests in physics which can be developed in Barbados—currently in progress are studies on some aspects of geophysics, aeronomy, meteorology and solar energy) IN PHYSICS at the University of the West Indies, Barbados—The Inter-University Council, 33 Bedford Place, London, W.C.1 (June 10).

TUTORS (2) IN PURE MATHEMATICS—The Registrar, University College of Wales, Aberystwyth (June 10)

CHAIR OF MATHEMATICS (Pure) at Chelsea College of Science and Technology—The Academic Registrar, University of London, Senate House, London, W.C.1 (June 15).

ASSISTANT LECTURER or LECTURER IN THE DEPARTMENT OF PHYSICS—The Registrar, The University, Liverpool, 3, quoting Ref. CV/46 (June 18).

RESEARCH ASSISTANT IN THE DEPARTMENT OF ZOOLOGY to participate in work concerned with the effect of antimetabolites on embryos—Dr. F. Billett, Department of Zoology, University of Southampton, Southampton (June 18).

LECTURER IN PHYSICAL CHEMISTRY—The Registrar, The University, Sheffield (June 20).

JUNIOR RESEARCH FELLOW (preferably with an interest in research in the area of laser flash spectroscopy) IN PHYSICAL CHEMISTRY—The Registrar, The University, Sheffield (June 30).

LECTURER (with a postgraduate degree and preferably some experience of teaching biochemistry at university level) IN BIOCHEMISTRY at Lincoln College, University of Canterbury, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, June 30).

MYCOLOGIST, SCIENTIFIC OFFICER GRADE (with a good honours degree) to work on soil-borne diseases of cereals—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (June 30).

SCIENTIFIC OFFICER or SENIOR SCIENTIFIC OFFICER (botanist, with a good honours degree and research experience) to study the physiology of sucrose storage in sugar beet—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (June 30).

LECTURER (graduate in science, with specialization in chemistry or biochemistry; in food science or home science) IN FOOD CHEMISTRY IN THE DEPARTMENT OF NUTRITION in the School of Home Science, University of Otago, Dunedin, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, July 15).

CHURCHILL PROFESSOR OF MATHEMATICS FOR OPERATIONAL RESEARCH—The Registrary, University Registry, The Old Schools, Cambridge, marking envelope "Confidential" (July 16).

LECTURER (with an honours degree in chemical engineering and some industrial experience) IN CHEMICAL ENGINEERING—The Registrar, University of Strathclyde, George Street, Glasgow, C 1.

LECTURER (with an interest in experimental psychology) IN PSYCHOLOGY—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

RESEARCH ASSISTANT (preferably with a good honours degree in biochemistry) IN THE DEPARTMENT OF PATHOLOGY to work in the Chemical Pathology Laboratories on biochemical aspects of ocular pathology—The Secretary, Institute of Ophthalmology (University of London), Judd Street, London, W.C.1.

SECOND CHAIR OF PHYSICS—The Academic Registrar, Northampton College of Advanced Technology, St. John Street, London, E.C.1, quoting Ref. P/N.

SENIOR TECHNICIAN and a TECHNICIAN TO WORK WITH AN EXPERIMENTAL IMMUNOLOGY GROUP IN THE DEPARTMENT OF ZOOLOGY—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh.

NO FRANKS AT M.I.T.

BY an irony that will no doubt give pleasure at All Souls, Oxford is not the only university having to reconcile its special position with educational good sense. A month from now, Dr. Julius Stratton will retire as president of the Massachusetts Institute of Technology after a long and distinguished association with the Institute as student, teacher and chief administrator. His impending departure has brought into prominence again many of the doubts which have plagued the Institute ever since it first became apparent that it is bound to be difficult—and challenging as well—to decide how best to balance the demands of a curriculum concentrated on technology and science and the need that a modern education should equip a person to work in the big wide world. As at Oxford so at M.I.T., the question is how best to make use of the institutional capital of a great university. So far, the Institute has done something to meet criticism about the treatment of undergraduates by grafting on to its strictly technical programme a certain amount of study in the humanities—units of study which range from modern languages to Greek and to what is called 'political science'.

On the face of things, it looks as if the M.I.T. Corporation is hoping for a permanent solution of some of its problems by sleight of hand. For Mr. Howard Johnson, who takes over from Dr. Stratton on July 1, is not a scientist in the accustomed sense but a man whose reputation is based on his outstanding work as dean of the Sloan School of Management at M.I.T. Nobody should hold this against the new president, even though it may be a disappointment that one of the more obvious (and not illiberal) candidates has not got the job. In any case, it is good to know that Mr. Johnson will have Dr. J. Wiesner as Provost. Indeed, there is the strongest possible case for a blending of technological and business studies in the style of Mr. Johnson's school. But it is all too tempting to suppose that the Corporation is expecting that the appointment of a man known as a social scientist may automatically guarantee that M.I.T. moves in the right direction. The inference may be wrong, of course, but so may be the calculation.

One of the troubles at M.I.T. is that, like Oxford, it is an *élite* university. Another is that it is not a university at all in the strict sense, but only a lopsided one. Undergraduates are required to dip into the humanities, but cannot plump for a degree in, say, history if they should find that subject more attractive than, say, physics. Women account for between 5 and 6 per cent of the undergraduate population, although the Institute would no doubt take in more if it could find sufficient able recruits. There are as many graduate students as undergraduates in the student body of 7,000. The ratio of faculty to students is more generous than the University Grants Committee would recommend in Britain, although comparisons are difficult because of the volume of government contract work at M.I.T. The euphemism for all this, which Dr. James Killian is always using, is that M.I.T. is "a university centred on science and technology". Why, then, is it always acting guilty?

The problems of teaching undergraduates properly in a predominantly graduate university are a part of the reason. A decade ago the Corporation was rightly alarmed to find that university teachers at M.I.T. were electing to send their sons (not to mention their daughters) to other universities instead of letting them run the gauntlet of undergraduate life at M.I.T. Now things are a lot better, but difficulties persist. The fast pace makes for competitiveness. Concentration makes things worse. The fact that the faculty is extremely talented does not guarantee that an undergraduate will not feel trapped on an intellectual treadmill from which he can only be released by getting into graduate school after four years of donkey work. Any leavening of the curriculum is obviously desirable, and by all accounts the humanities programme has already brought benefits of morale as well as of breadth. It remains to be seen whether these well-intended innovations are sufficient—and whether they will serve somehow to make less solemn the undergraduates who are still easy sport for B.B.C. television cameras.

Another class of problems stems from the scale and character of undergraduate work at M.I.T. It is natural (and right) that an institution bent on technical training of the highest quality should seek to set its graduates and faculty members real problems for research. One splendid result has been the way in which M.I.T. has spawned successful industries based on science throughout Massachusetts and beyond. The other side of the coin is that the Institute has allowed itself to be overweighted with work that must be a distraction even for a university determined to be useful. In particular, the volume of defence research at M.I.T. may well be too much for comfort. It is always difficult to estimate when a Government research contract is an educative incentive for those engaged on it, and when it becomes an administrative bore, but M.I.T. may have put itself at the disposal of the U.S. Government too readily for its own good and, in the long run, for the Government's. The truth is that M.I.T.—for an *élite* university—is surprisingly lacking in public influence. Killian, Wiesner and Samuelson, to mention only some, have immense personal influence, but the corporate body has been far less influential than its talents could have made it. Yet M.I.T. is well placed to influence decisively the pace and the direction of change in science and technology. Paradoxically, perhaps, that could easily give the undergraduates something more glittering to work for than a chance to work hard at graduate school.

So what should Mr. Johnson do? The first thing to agree is that there are limits to what the humanities can accomplish at M.I.T., at least so long as they remain peripheral. Either Mr. Johnson must go the whole hog, and offer degrees in the humanities, or he must tackle the undergraduate problem more directly. On balance, the second course is preferable. Whatever defects there may be, the present system at M.I.T. has a number of outstanding merits. It has, for example, virtually obliterated the distinction between science and technology, and the new president is lucky that there are already under way important innovations in the self-conscious development of undergraduate curricula. These are important assets on which to build.

A lot can be done within science and technology themselves. Making economics an integral part of the curriculum will be an obvious innovation for Mr. Johnson, but none the less valuable on that account. With its

good supply of able students, the Institute is also well placed to experiment with studies which span conventional boundaries. But it would be still more exciting if it were to attempt to work out ways of giving technology a more purposeful place than it has at present in modern society. Why should not M.I.T. concern itself as much with the problems of urban technology as with those of reaching the Moon? Ideally, Mr. Johnson should set out to give M.I.T. the means of helping society to decide what uses to make of science and technology. His predecessors have accomplished a lot already, but a great deal remains to be done.

MORE BUREAUCRATS

SO far as it goes, the report of the Civil Service Commissioners for 1965 is cheerful about the recruitment of scientists to the British Civil Service. Of the 107 candidates successful in the competition for entry into the Administrative Class—the members of which eventually come to inhabit what are called the corridors of power—no fewer than nine are said to be endowed with a scientific training. The Commissioners say that this was a "marked improvement" on previous years, but plainly there is a long way to go before present methods of recruitment will ensure that the mainstream of the Civil Service is adequately supplied with competent scientists. At the same time, there is continuing anxiety about the recruitment of capable scientists into the Scientific Class. Here the difficulty is not so much an absolute shortage of numbers as a shortage of candidates of really outstanding quality. This does not necessarily mean that the Government research establishments are starved of really able men, for the recruitment of professional scientists to the Civil Service usually entails a period of unestablished service which does not count in the Commissioners' statistics. But evidently there is a lack of really able professionals willing to settle down in Government service. Even though the rapid growth of recent years is clearly part of the cause of the Commissioners' anxiety, things could obviously be better than they are.

Here, as in many other parts of British public administration, the remedy is probably to be found in greater flexibility. Thus the recruitment of scientists to the Administrative Class would be enormously improved if only the Civil Service as a whole would make fuller use of the arrangements which now exist for the transfer of men and women from one class to another. In 1965 there were fewer than a dozen transfers of this kind, yet the Government laboratories are now well supplied with experienced administrators ready and able to spread their wings. Both classes—the Administrative and the Scientific—would be better off if there were a more ready interchange between them. In a very similar way, recruitment to the Scientific Class would be improved if it were easier than it is at present for professional civil servants to retain a sense of kinship with the scientific discipline to which they belong. There needs to be a greater traffic of people between the research establishments and the universities and industry. Sabbatical leave ought to be a necessity, not a luxury. And some of the humdrum customs of public service ought to be abolished. The irony is that British public laboratories have never before been so well stocked with exciting problems to be tackled.

COMMONSENSICAL ENGLISHMEN

The English Paracelsians

By Allen G. Debus. (Oldbourne History of Science Library.) Pp. 222+7 plates. (London: Oldbourne Book Co., Ltd., 1965.) 45*s*. net.

THE sixteenth century was rich in passionate personalities who delighted in being at the storm centre of controversy and whose life and work have aroused either adulation or distaste ever since their own day. Was Cardan, the astrologer-physician, a great mathematician or a fraudulent plagiarist? Was Giordano Bruno a Copernican martyr or a magician and pantheistic heretic, Paracelsus the founder of modern chemistry or an alchemist sunk in mystic and incomprehensible theory? It all depends on one's temperament, and neither Paracelsus nor any of the others have ever lacked defenders. Those who find these mystic and magical aspects of the sixteenth century distasteful and of doubtful value in the history of modern thought can console themselves with the reflexion that the later contemporaries and successors of those followers of the Hermetic tradition (as Frances Yates has recently taught us to consider it) found their books difficult to understand and even nonsensical.

Mr. Debus belongs to the younger generation of historians of science, already in revolt against the rationalist views of his post-War predecessors; he would like to see in Paracelsus a dominant leader in the emergence of modern chemistry. Had he chosen to discuss the Continental Paracelsans of the period before 1650 he would have found, as he himself says, much detailed and solid evidence of Paracelsan influence. But circumstances have led him to write about Paracelsanism in England before 1640, and he is too good a scholar not to recognize that the English even then were too sceptical of high-flown mystic or metaphysical theory to be Paracelsans in any real sense, and, as here emerges, Paracelsan ideas were of negligible importance in Elizabethan and Jacobean England.

It must be remembered that then, as now, Paracelsus was a very inaccessible author. Few Englishmen could (or can) understand the curious mixture of Schweizdeutsch and Latin in which Paracelsus wrote, and most of his works have never been translated into English. (Only two small works were so translated in this period.) In addition, Paracelsus's theory is difficult to understand; he expressed himself obscurely and is often inconsistent. Only two Englishmen ever seem to have been direct followers of Paracelsus: Bostocke and Fludd. (More refer to his theory only to insist they cannot understand it, and a few accepted a diluted version promulgated by later Continental Paracelsans.) Bostocke was an extremely obscure Elizabethan mainly remembered for his comparison of Copernicus and Paracelsus (which Mr. Debus makes less clear because he does not know the Elizabethan usage of 'stars' for 'planets'). Robert Fludd, whom Mr. Debus has studied at some length, was the Jacobean expositor of a 'Mosaic philosophy', a blend of Renaissance science and speculative mysticism which was extensively attacked on the Continent, notably by Mersenne and Gassendi, but was virtually ignored in England. The mystic chemistry to be found in this period belongs to the older alchemical tradition of George Ripley and Thomas Norton; it was not until the 1650's that English mystic chemistry received a new stimulus from the work of Van Helmont. It is to be hoped that Mr. Debus may give us an examination of English Helmontians, who are many and varied.

As *The English Paracelsians* amply demonstrates, English medical men and apothecaries accepted the 'new' chemical remedies and drugs for which Paracelsus had claimed so much without regarding them as necessarily Paracelsan. Partly this is because they recognized that chemical remedies were older than Paracelsus, and partly because they derived them from followers of Paracelsus in whom the pure Paracelsan doctrine was much diluted.

Mr. Debus discusses the influence of Quercetanus (known to his contemporaries exclusively by this Latin form of Duchesne) who wrote in Latin (so that he was accessible to the learned) and whose works were also speedily translated into English. But he does not mention Basil Valentine (some of whose works were available in Latin in this period) nor the text-book of Jean Beguin, well known in England, and does not seem to appreciate the importance of Oswold Croll, very influential for the reliance on chemical drugs which developed in this period. In fact, chemical remedies seem to have crept into the English pharmacopoeia without great opposition; the great battle between the orthodox College of Physicians and the Society of Chemical Physicians belongs to the 1660's. One cannot help wishing that, on all counts, Mr. Debus will choose to write another book on English medical chemistry after 1640; it would surely provide more scope for his scholarship, more important and influential books than those examined here, and some opportunities for dipping into the manuscript sources. This is an effective account of the way in which English medical writers before 1640 accepted medical chemistry while rejecting Paracelsan mystic theory; but the history of common sense cannot be by its nature intellectually exciting.

MARIE BOAS HALL

SOUTH OF THE BORDER

Latin America

An Economic and Social Geography. By Dr. J. P. Cole. Pp. xviii+468. (London: Butterworth and Co. (Publishers), Ltd., 1965.) 57*s*. 6*d*.

A RECENT development in many British universities, both new and old, is the institution of courses or schools in area studies. In particular there is renewed attention to Latin America, where British capital played so large a part in such early developments as railways, ports and trade. There followed a long period, perhaps of disillusion, when Latin America was much neglected, both in commercial circles and in academic studies. The renewed interest recognizes the vast potential of one of the least-developed world regions—14 per cent of the Earth's land surface, but only 7 per cent of world population.

Dr. Cole, at present lecturer in geography in the University of Nottingham, has travelled in most of the Latin American countries—by which he includes all the New World south of the United States border—over a period of 10 years, and in so doing has acquired a good working knowledge of Spanish and a Peruvian wife. He makes the latter his excuse for naïvely apologizing to his readers for a possible over-emphasis on Peru.

Recognizing that there are some excellent general text-books on the geography—notably Preston E. James's *Latin America*, which has been described as one of the best geographical descriptions of any area in the English language—Dr. Cole wisely concentrates on a snapshot picture of the early sixties, in which he relies heavily on the census returns of 1960–61 and the statistical information collected by United Nations agencies. Almost half *Latin America* is devoted to Latin America as a whole—population, physical background and resources, history, present political and economic development, transport, agriculture, mining and manufacturing—the remainder to a treatment by countries. Throughout the book there are certain unusual features. Many of the very large number of simple thematic maps or cartograms ignore the conventional north–south orientation: indeed, Latin America as a whole can be shown with economy of page space if depicted obliquely. However, even the initiated may be forgiven for hesitation in recognizing the U.S.S.R. shown (for comparison) on end. There are no photographs; instead the author's father, Mr. P. Cole, has skilfully translated photographs into effective line drawings.

Dr. Cole recognizes that he is writing not only of a vast and very varied area but also one in a state of rapid evolution. At present no political unit in the world can show the range of conditions exhibited by Brazil—from literally unexplored depths of the Amazonian forest to the ultra-sophisticated life of skyscraper São Paulo, Rio and Belo Horizonte, or the imaginative creation of Brasilia, but daily new motor highways are being pushed across the 3 million square miles of national territory. As the long-discussed Pan American Highway becomes a reality so the Latin American Free Trade Association assumes a major significance. The final chapter is appropriately devoted to foreign trade and economic union. The total value of Latin American foreign trade in 1961 was 17,210 million U.S. dollars with exports worth slightly more than imports, which may be compared with United States foreign trade for the same year of 35,323 million dollars. It comes as a surprise, perhaps, to find that Venezuela leads the nations with 20 per cent of the whole, but this serves to emphasize the huge importance of oil. Oil in fact accounts for 28 per cent of the total exports of all Latin America: it is followed by coffee, 17 per cent.

It is perhaps invidious to pick these few details from a book that is packed with information, well presented, and commendably up to date. L. DUDLEY STAMP

PNEUMATIC CONTROL DESIGN

Components for Pneumatic Control Instruments

The Static and Dynamic Characteristics of Pneumatic Resistances, Capacitances and Transmission Lines. By L. A. Zalmanzon. Translated by R. Hardbottle. Translation edited by F. P. Stainthorp. Pp. xv+321. (London and New York: Pergamon Press, Ltd., 1965.) 110*s*. net.

COMPONENTS for Pneumatic Control Instruments is a misleading title, in that it might lead one to expect detailed description of the wide range of pneumatic components used in process control. The sub-title gives a better clue to the contents and, within the limits indicated by the sub-title, the coverage is comprehensive. There is room for a range of books of this standard under the main title, each covering a limited number of specialized topics.

The process control engineers with their pneumatic controllers were pioneers in automatic control. Because of the early development of the three-term-controller with its wide range of adaptability, there was no urgent need for detailed analysis of design and process, and thus to some extent progress slowed down on pneumatic while hydraulic and electrical systems became the centres of interest. If the pioneer does too well initially he may satisfy immediate demands but fail to develop quickly enough as demands increase.

While the major factors in the development of control systems were, of course, the requirements of the process industries and of the armed services, an important factor is the educational equipment of the designers. Most engineers are well qualified to extend their knowledge in the fields of general mechanical and electrical engineering including hydraulics and electronics; but only a few study aerodynamics, and some of the basic ideas of aerodynamics are essential to the development of pneumatic theory. This book should satisfy the need and is timely since pneumatic control is well into its second stage of development, which includes general applications, transmission of information, optimization and certain logical and computational functions.

The sub-title gives an admirably precise description of the contents. The chapters are headed "Theory fo Restrictions"; "Pneumatic Chambers—Static Characteristics"; "Dynamics of Pneumatic Chambers"; and

"Characteristics of Long Pneumatic Lines". Some useful data from aerodynamics is given in a thirty-page appendix. Restrictions are categorized as turbulent, laminar, and mixed flow types for the purpose of analysis and there is an interesting study of the effect of the eccentricity of the plug in an adjustable restriction. Pneumatic chambers are dealt with as flow and blank chambers in combination with restrictions and in a variety of banking arrangements. This section is rich in design data and gives several examples of design calculations. As for the chambers, the dynamic equations for long pipe-lines are derived and these equations are solved by methods analogous to those used for electrical transmission lines.

The book is written for the designer. While adequate theory is given when required, the plan is rather to state and explain formulae and give references to published work. It is a comprehensive review of knowledge in a limited field and presents this knowledge in a way which makes it readily available for design use. The bibliography has exactly a hundred references (ten to work by Zalmanzon), mostly to publications dated from 1950 and the most recent dated 1960, which is as new as can be expected since the original volume was published in 1961. Many of the references are to Russian papers and the titles of these are helpfully translated. There is no index other than a subject index of some sixty items, but this is not a serious lack since the contents are given in detail.

W. McHUTCHISON

PLANT-GALLS OF EUROPE

Bestimmungstabellen der Gallen (Zoo- und Phytocecidien) an Pflanzen Mittel- und Nordeuropas

Band 1. By Dr. phil. habil. Herbert Buhr. Pp. xvi + 761. (Jena: VEB Gustav Fischer Verlag, 1964.) 139*s.* 9*d.*

IF one were to describe this exhaustive treatise on the plant galls of Central and Northern Europe as a typical example of Teutonic thoroughness, it would be but to pay tribute to the undeniable German genius for this type of encyclopaedic production.

Bestimmungstabellen der Gallen (Zoo- und Phytocecidien) an Pflanzen Mittel- und Nordeuropas is arranged in the way which has been customary in previous systematic cecidological works, that is, strictly alphabetically by host genera; the first volume covers the genera *Abies* to *Myrrhis*. Cryptogamous hosts (algae, fungi, lichens) are also included. The information, though presented in key form, is rendered considerably more accessible and usable than is often the case with an amalgamated key-plus-description presentation by the judicious use of large and small type and other distinctive type-faces, combined with paragraphing and generous spacing. In his preface, the author expresses his appreciation of the co-operation which he experienced from his publishers and printers; and indeed author, publisher and printer alike deserve commendation for the evident care and thought that has been given to lay-out and production. The subsidiary small-type paragraphs under each gall-description include notes on distribution, bionomics, etc., together with copious references to literature.

The keys are preceded by a 64-page introductory section ("Allgemeiner Teil"), in which general aspects and problems of cecidology are discussed. Several pages are devoted to gall aetiology. "Galls arise in the course of mutual action and counteraction between the partners [host and parasite], in a constant opposition between normal and abnormal growth, as a compromise solution. All formative impulses originating from the parasites can only set in motion in the plants processes which fit into the framework of their hereditarily conferred morphogenetic capabilities." There is as yet, however, no agreement between authorities concerning the relative parts played in gall-formation by growth-promoting substances produced by the host-plant itself and by specific substances secreted by the parasite. Attention is directed to peculiar features in the biology of certain galls and their producers, such as the remarkable phenomenon of 'chlorophyll-conservation' in certain poplar-feeding *Stigmella* species (Lepidoptera) where the activity of the leaf-mining larva causes a retardation of the normal process of senescence in the surrounding tissues, which thus remain green until the larva has completed its development. In another section the author discusses the question, What is a gall? He also details methods for the study and preservation of galls and their causative organisms.

The work is illustrated (at the end of Volume 2) by twenty-five plates, containing 443 figures, many of which are taken or re-drawn from Dunzinger's illustrations to the well-known work of Ross and Hedicke (1927), or from the more delicate drawings by Han Alta illustrating Docters van Leeuwen's much more recent (1957) handbook to the plant-galls of The Netherlands.

Prof. Martin Hering, the authority on leaf-miners, in his foreword directs attention to the fact that Dr. Buhr has not only dealt with galls of animal origin, but, unlike all his predecessors in the field, has also included those caused by fungi and other plant-parasites. This gives a unique value to the work. Prof. Hering also tells us that the author has devoted special care to providing the taxonomically and nomenclaturally correct names for the organisms mentioned.

On all counts, one must agree whole-heartedly with the claim of the publishers that this remarkable single-handed production, the crown of a life-work of botanical, pharmacognostic, zoological and phytopathological study, represents a "unique scientific achievement".

H. K. AIRY SHAW

SUGAR CANE RESEARCH

Genetics and Breeding of Sugar Cane

By G. C. Stevenson. (Tropical Science Series.) Pp. xi + 284 + 51 plates. (London: Longmans, Green and Co., Ltd., 1965.) 70*s.* net.

IT is a truism that if a crop is important, the interests which it serves, whether industrial or agricultural, usually spend a great deal of money on research. Such research is often carried out in special research institutes concerned only with one crop; this is the case with sugar cane, sugar beet, rubber, tea, coconuts, etc. This is as it should be, for if a crop has to compete with other crops for funds in an experimental station, it tends to suffer from lack of men, money, and equipment.

Genetics and Breeding of Sugar Cane is the third in the *Tropical Science Series*, the volumes of which serve to present detailed information about tropical crop plants. Such information is widely scattered in a large number of publications often hard to obtain.

The book has eight chapters, dealing respectively with taxonomy; the history of sugar cane improvement; flowering and its control; breeding methods; variation and inheritance; cytology; and breeding systems. There is a final chapter on "The Philosophy of Sugar Cane Breeding" which should be compulsory reading for all students of applied genetics.

The breeding methodology of any plant is dominated by a number of special features. In sugar cane these are: the enormous number of seedlings which can be raised, making it possible to screen adequately for resistance to pathogens, and to establish rigid standards for selection; the existence of several species with wide geographical extension and consequently a wide range of adaptability; and the extensive production of unreduced gametes, making possible the important phenomenon of the addition of genomes (nobilization).

Surveying the sugar cane world from China to Peru, the author has extracted the relevant information about all these aspects from a great number of sources. He has not been content with the mere bald presentation of the material, but has made full use of his thirty years' experience of the crop to comment in detail and to criticize constructively. If there is a fault, it is that the book should have been twice as long and much more information might have been given on how a breeding programme is actually executed. The chapter entitled "Breeding Methods" gives details of techniques rather than the methodology of breeding.

The fact that research on sugar cane is mainly, though not always, paid for by industry has inevitably led to a not unreasonable demand for more or less immediate practical results. These are certainly impressive since, as the author points out, sugar yields in some countries have been more than doubled within the past twenty-five years. At the same time, one gets the impression that although much fundamental work has been carried out, it has often been a by-product of work dictated primarily by economic considerations, and organized for economic results. Thus, apart from the author's own important work, there has been little work on the production of pure lines, a procedure almost essential in a long-term breeding programme. Whether apomixis occurs seems to be still in doubt. If it occurs, even though rarely, it would be of great importance to the breeder. There does not seem to have been any organized attempt to produce haploids—also important in long-term work.

The sugar industry is wealthy and if it could be induced to carry out fundamental research on genetics and physiology without the spectre of profits looming large, the long-term benefits might be unexpectedly great.

This book is essential for all sugar cane workers, and it contains lessons for breeders of other vegetatively reproduced crops. Readers will be grateful for the literary style of the author, which is at once elegant, lucid and clear.

S. C. HARLAND

STARCH: ITS FUNDAMENTALS AND POTENTIALITIES

Starch

Chemistry and Technology. Edited by Roy L. Whistler and Eugene F. Paschall. Vol. 1: Fundamental Aspects. Pp. xviii+579. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) 22 dollars.

VOLUME 1 of *Starch: Chemistry and Technology* describes the more fundamental aspects of starch chemistry and technology and sets the scene for a second volume, which will cover industrial aspects. There is much that is described here that has yet to be exploited by industry, most of all on the biological side, the fundamental advances in which have been practically without impact on industry. Two exceptions come to mind; first, the growing 'takeover' by amyloglucosidase from acid as a means of converting starch into glucose; and secondly, the selective breeding of maizes rich in high-amylose or high-amylopectin starch. The full potentialities of biology to the starch industry are very far from realization.

Of all sources of organic raw material, starch offers the major opportunity to the industrialist in search of new products. The demand for starch as the largest single item of diet ensures its continuing supply at steady prices, but the shrinking *per capita* consumption of starch in Europe and North America has meant that its output for food purposes has only been kept from serious shrinking by population increases. In the post-war era, the non-food uses of starch, such as for adhesives and sizing, have met severe competition from other natural or synthetic polymers. The starch industry in the United States has reacted by vigorously pursuing research into new products for food or non-food uses. In the main the attack has been through chemical modification of starch, for example by cross-linking or by oxidation, to impart desirable physical properties. An example of a new product is the use of amylose as an edible film for food packaging. The economics of the process, in the form of the present price of amylose, would seem to represent the only bar to what could be a very large exploitation. Glucose production by enzymatic hydrolysis has already been mentioned, and the real possibility of a cheap enzymatic method for the partial conversion of glucose into the much sweeter fructose, to produce an 'artificial' invert sugar, could well make considerable inroads into the sucrose industry, which has already felt the pinch from glucose alone as a sweetening agent. Given the investment in research, the starch industry need not fear any slackening of demand for its products. Indeed the second chapter in the book under review, by P. L. Farris, predicts "a probable doubling of the market for starch between 1960 and 1980". At the same time, R. L. Whistler, in the introductory chapter, foresees a corn (maize) crop of 300 bushels per acre, against the present United States average of 62·4 bushels. In the rest of the world the present average yield is only 30·2 bushels per acre.

The chapters that follow describe genetic control of starch development; occurrence and development of starch; minor constituents; enzymatic synthesis and hydrolysis; oligosaccharides and *cyclo*amyloses; chemical evidence for structure; crystallinity; gelatinization; organic complexes; fractionation; properties of starch fractions; paste properties; radiation; pyrolysis; non-degradative reactions; and acid and alkaline degradation. The authors, with one exception, are drawn from United States industry and research institutions and are well known and respected.

This and the second volume are intended as successors to the classic compilations by R. W. Kerr. The multiple authorship and the increase in size over Kerr only reflect the greatly increased knowledge of the subject. The coverage of the fundamental aspects is generally well balanced and much previously unreviewed material is gathered, for example on the *cyclo*amyloses (Schardinger dextrins). These particular substances represent a real challenge to industry, for they could be produced very cheaply if required on a large scale. The Schardinger dextrins form inclusion compounds, often crystalline, with every conceivable class of compound, from iodine to bromobenzene, tyrosine and helium. This property must surely find a commercial outlet.

A serious omission from the book is any description of the evidence for starch structure as obtained by the use of enzymes. It is impossible to describe the presently accepted structures of amylose and amylopectin without drawing on the evidence of enzyme action, notably of β-amylase. Indeed, present chemical methods of analysis are, by themselves, inadequate even to elucidate the structures of relatively simple oligosaccharides obtained by degradation of amylopectin, let alone the polymer itself. The Meyer, Staudinger and Haworth formulae for amylopectin have always been presented in a way that takes account of our knowledge of β-amylase action. If one took no account of enzymatic evidence, each of these formulae could be written in a wide variety of ways and many additional formulae could be written that are not excluded by chemical evidence alone. This reservation apart, the book can be recommended as indispensable to anyone with any kind of scientific interest in starch. It reviews the field essentially up to 1963. The documentation is thorough, and the abundant numerical data considerably enhance the value of the book as a work of reference. The senior editor, Prof. R. L. Whistler, has added another notable contribution to his authorship and editorship of works of reference on carbohydrates.

W. J. WHELAN

ON THE INTERPRETATION OF THE LINE SPECTRA OF QUASI-STELLAR OBJECTS

By PROF. G. R. BURBIDGE and PROF. MARGARET BURBIDGE
University of California, San Diego
PROF. F. HOYLE
University of Cambridge and California Institute of Technology
AND
DR. C. R. LYNDS
Kitt Peak National Observatory

IN the past 2 years several investigations of the spectra of the quasi-stellar objects have been made so that at present more than forty objects have been observed in sufficient detail for identifications and thus red-shift measurements to be made. In Table 1 we give a compilation of the general properties of the line spectra of these objects, while in Table 2 we give details of the specially rich spectrum of 3*C* 191. So far, attempts have been made to determine the physical conditions in the emitting gas using the line and continuous spectra of 3*C* 48 and 3*C* 273 by Greenstein and Schmidt[1] and by Shklovsky[2]. They have shown that the regions emitting the line spectra in these objects are somewhat similar to the emitting regions in planetary nebulae, that is, electron densities $N_e \approx 3 \times 10^4$–$10^7$ per cm^3, and electron temperatures $T_e \sim 10{,}000°$–$30{,}000°$ K. Now that objects with z up to about 2 have been studied, the main characteristics of the line spectrum of a 'standard' quasi-stellar object in the wave-length range $\sim$1100–7000 Å are available and are contained in Table 1. Estimates of the computed line strengths for different assumed values of N_e and T_e have recently been given by Osterbrock and Parker[3].

Because the spectra of such faint objects can only be obtained with low-dispersion nebular spectrographs, and because the features are frequently weak and diffuse, only very crude estimates of line strengths for the majority of quasi-stellar objects are as yet available.

We shall concentrate here on attempting to account for the widths of the lines and the different stages of ionization which are seen. It should be borne in mind that our standard quasi-stellar object is obviously a composite model, and only extension of the wave-length range of observation will determine to what extent the gaseous envelopes of the individual objects are very similar.

Line Widths

In previous investigations it has been assumed that the great widths of certain of the observed emission lines are due to mass motions in the envelopes, and little attention has been directed to the possibility that the widths are due to electron scattering (in the paper of Greenstein and Schmidt a comment about electron scattering is made in a footnote). However, the discovery that in the case of 3*C* 191 a narrow absorption line spectrum is present[4] shows that at least in the region giving rise to the absorption lines which have widths (corrected for red shift) of $\leqslant 3$ Å the mass motions must be small. Moreover, in this object systematic motions of the emitting region relative to the absorption line region are also shown to be less than a few hundred km/sec. The absence of absorption lines in resonance transitions in the spectra of other quasi-stellar objects can indeed be understood if mass motions are still smaller than is the case in 3*C* 191.

Our suggestion is that the large widths of the emission lines in the quasi-stellar objects arise from electron scattering, and we shall now consider the range of line widths that have to be accounted for and show that, under the physical conditions indicated by the emission lines that are present, electron scattering can provide sufficient broadening.

Because of the graininess of the observed continuum on the photographic plates, the width to be attributed to a line is to some extent a matter of subjective judgment—the estimates of Table 1 are to be interpreted in that sense. In some cases widths in angstroms are given, and in others the symbols w, m, n are used; approximately, w indicates widths of 40–100 Å; m, widths of 20–30 Å; and n, widths of 10–15 Å. From Table 1 we see that in the majority of the quasi-stellar objects the emission lines are broad with widths estimated to lie in the range 30–50 Å. Some of the widest lines are Lyman-α (Ly-α), C IV λ1549, and Mg II λ2798. In some cases the forbidden lines are narrow ($\leqslant$ 10 Å).

In order to decide what width a line should have it is necessary to take account of the nature of the line—whether it is permitted or forbidden—and also to give estimates of the optical depth τ_e against electron scattering and the electron temperature T_e. In the case of permitted resonance lines such as Mg II λ2798 it is not necessary for the optical depth τ_e to be comparable with unity in order that the line be so broadened. For such lines quanta are emitted and reabsorbed in sequence until electron scattering out of the line centre occurs. The opacity to perhaps ± 3 Å from the line centre is large, and not until electron scattering takes the quanta sufficiently off resonance can they escape from the system.

In order to consider the magnitude of the width due to electron scattering we have adopted the following procedure. We take a line to have disappeared into the continuum when its intensity has declined to a third of what it is, not at the centre, but at 3 Å from the centre. We then use the computations of the electron scattering line profiles by Münch[5] and find that a width $\simeq$20 Å is obtained for an electron temperature of 10,000° K, $\sim$30 Å for $T_e \approx$ 30,000° K, and $\sim$50 Å for $T_e \approx$ 100,000° K. The width is not exactly proportional to $T_e^{\frac{1}{2}}$ because of our procedure of comparison with points 3 Å from the line centre; 3 Å is a different fraction of the width in the different cases. For a really strong line this procedure underestimates the width—an intensity decline to about a sixth would then be more appropriate, nearly doubling the width. For the long path lengths which quanta in strong permitted lines such as Mg II λ2798 and Ly-α will traverse before finally escaping, it is thus clear that great widths can be produced by electron scattering at electron temperatures of 10,000°–30,000° K.

In the case of forbidden lines such as [O III] λ5007 the argument is different because an ion which gives rise to a forbidden line does not supply a high opacity near its resonant frequency. To broaden a forbidden line τ_e must

be ~ 1. Again using the results of Münch, we estimate for $\tau_e = 0{\cdot}8$ a width ~ 40 Å at $T_e \approx 30{,}000°$ K, and a width ~60 Å at $T_e = 100{,}000°$ K. In the cases in which narrow forbidden lines are seen, we conclude that τ_e must be small. The general tendency appearing in Table 1 for the lines from permitted ground-level transitions to be wider than the forbidden lines is an argument in favour of the electron scattering hypothesis. We also call attention to 1217 + 02, in which [O III] λλ 4959 and 5007 are much narrower than [O III] λ4363; the first two lines arise from a level of 2·50 eV excitation, and the latter arises from a level of 5·33 eV excitation. This strongly suggests a broadening agent which is a function of depth in the object, the λ4363 line being produced deeper than the λλ 4959, 5007 lines. Electron scattering provides a natural explanation, while mass motions do not.

Finally, we note that in a model for 3*C* 273 based on measurement of the continuum flux, Oke[6] has proposed a very high value of the electron temperature, up to ~160,000° K, in order to obtain the small Balmer discontinuity which is seen. But at such a high temperature, broadening by electron scattering would always be large, particularly for the resonance line Mg II λ2798.

A Model to explain the Different Ionization Stages observed

We propose a three-zone model with the following properties:

(I) Optically thick to quanta with $h\nu > 13.595$ eV.

(II) Optically thick to quanta with $h\nu > 54.403$ eV.

(III) Optically thick to quanta with $h\nu > 24.581$ eV.

It is implied that in zone I the gas is thin to quanta of energies less than the Lyman limit, while in zones II and III it is thin to quanta below the ionization potentials of He^+ and He respectively. (The reason why we have apparently inverted the order of the helium ions will appear at a later stage.) We regard these conditions as being imposed by the hydrogen and helium. Zone I is an H I region. Zone II is an H II, He II region, while zone III is an H II, He I region. In all zones, lines other than those due to hydrogen and helium are produced by excitation of their upper levels by electron collisions. The hydrogen and helium lines are produced by recombination.

Zone I is necessary to explain the presence of the Mg II emission. The ionization potential of Mg^+ is only 15·031 eV and this ion can exist in appreciable abundance only in an H I region. It is an attractive possibility that Mg II λ2798 might be produced by recombination of Mg^{++} in an H II region. The big gap between the ionization potentials of Mg^+ and Mg^{++} (the latter has an ionization potential of 80·12 eV) would lead to a big build-up of Mg^{++}. However, the recombination coefficient of Mg^{++}, which is not known, would need to be greater by a large factor than that of H^+ to overcome the abundance difference and give comparable Ly-α and Mg II λ2798. In zone I the most abundant ionization stages of the common elements are: H, H^+, C^+, N, O, Ne, Mg^+, Si^+, S and Ar. The important lines to be attributed to these ions[7] are H I (Ly-α, Hα, - - -), C II (λλ 1335, 2325), N I (none), O I (none), Ne I (none), Mg II (λλ 2796, 2803), Si II (λλ1190, 1193, 1194, 1197, 1260, 1265, 1304, 1309, 1527, 1534, 1808, 1817, 1818, 2329, 2335, 2345, 2351), S II (λλ 1227, 1233, 1234, 1250, 1254, 1259), Ar I (none). (The notation (none) simply means that in Osterbrock's list[7] of the lines which are expected there is none from the ions in the spectrum range covered.)

The C II and S II lines are seen in absorption in 3*C* 191, as also are the Si II lines shortward of 1500 Å. The lines of C II, S II, Si II are not seen in emission, however, with the exception of C II λ1335 in 3*C* 280·1 and C II λ2325 which is observed weakly in 3*C* 208; Si II λ1817

The spectroscopic material and the red shifts z have been assembled from results given in refs. 1, 4, 8, 9, 11–20, and from unpublished observations of two of us (C. R. L. and M. B.). The apparent visual magnitudes in the second column are mainly from the work of A. R. Sandage *et al.* (and are in general variable).

The nomenclature is as follows: line strengths are given first for each entry, with *W*, weak, *M*, medium, *S*, strong, *v*, very; widths are given second after a comma, with *w*, wide (40–100 Å), *m*, medium (20–30 Å), *n*, narrow (10–15 Å); in many cases actual widths have been estimated, usually from Lynds's spectra. When a line has been measured but no information on its width or strength is available, an asterisk is given.

The table has been divided into two parts to save space, objects with $z<1$ being in Table 1*A* and those with $z>1$ in Table 1*B*. For $z<1$, lines with rest wave-lengths shorter than O III] 1663 are not shifted into the observable range. Similarly, for $z>1$, lines of long wave-lengths are red-shifted beyond the region normally studied. Since the lines [Ne V] λ3346, [Ne III] λ3968, [O III] λ4959 are weaker members of doublets the stronger lines of which are not included in the table, they add no new information and therefore are not included.

FOOTNOTES TO TABLES 1*A* AND 1*B*

(*a*) Balmer lines Hα (*vS*, *w*), Hδ, He also seen.
(*b*) Hγ, [O III] λ4363 blended. Additional lines seen at 2830 Å (He I ?).
(*c*) Hγ, [O III] λ4363 blended.
(*d*) Mg II λ2798 not seen. Magnitude corrected for interstellar absorption.
(*e*) Weak Hδ also seen. Hγ, [O III] λ4363 blended.
(*f*) Mg II λ2798 complex and variable. Affected by He I λ2829 ?
(*g*) Hydrogen lines seen; weak.
(*h*) Magnitude corrected for interstellar absorption.
(*i*) C II] λ2327 possibly present.
(*j*) Mg II λ2798 complex.
(*k*) Very weak [Ne V] λ3426 also seen.
(*l*) C II] λ2327 also measured; weak.
(*m*) Self-absorption in C IV λ1549.
(*n*) Absorption dominates in C IV λ1549.
(*o*) Deep absorption in shortward wing of C IV λ1549.
(*p*) Both SiIV λ1394 and [OIV] λ1407 emission lines seen; emission lines of C II λ1335 and N IV] λ1438 definitely present; Si II emission lines possibly present.
(*q*) Numerous narrow absorption lines seen, C IV 1549 being the strongest. Only emission lines are listed here.
(*r*) Self-absorption in shortward wing of Ly-α and C IV 1549.
(*s*) Absorption in shortward wing of Ly-α. Absorption at 1150 Å, none at 1460 Å. Weak emission from N II λ1085.

Table 2. LINES IDENTIFIED IN THE SPECTRUM OF 3*C* 191

may be present weakly in 3*C* 280·1. In some cases the absence of emission lines can be understood in terms of the abundances of the ions and of the electron excitation cross-sections. For example, the probability of exciting the Si II multiplet at λ2329 Å by electron impact is less than that of exciting the Mg II doublet by a factor of more than 50. The critical case is C II λ1335. This line has a large excitation cross-section. Moreover, carbon is expected to be appreciably more abundant than magnesium. How, then, do we explain the fact that C II λ1335 is observed in emission in only one of our list of quasi-stellar objects, whereas the Mg II doublet is often strong? Only, it seems, by taking the electron temperature to be low. The energy difference between 1335 Å and 2798 Å is ~ 4·8 eV, so that the number of electrons capable of exciting Mg II λ2798 exceeds the number capable of exciting C II λ1335 by exp $(4{\cdot}8/kT_e)$ where kT_e is measured in eV. For $kT_e \approx 1$ this is a factor exceeding 100, which is sufficient to exclude C II λ1335. With $T_e \approx 10{,}000°$ K the width of the Mg II doublet should be ~ 20 Å in average cases, and extending upward of 30 Å for strong Mg II emission. How does this compare with the observed widths? From Table 1 it is seen that a width of 20–30 Å for the Mg II doublet agrees with observation for the following cases: 1217 + 02, 3*C* 277·1, 3*C* 215, 3*C* 47, 3*C* 334, 3*C* 275·1, 3*C* 380 and 4*C* 39·25. The seriously discrepant cases are: 3*C* 279, *MSH* 03–19, 3*C* 261, 3*C* 286, 0922 + 14, 0957 + 00, and *MSH* 14–121. These discrepant cases would seem to require the light from the Mg II doublet to pass through a region of higher temperature with $\tau_e \simeq 1$. This would have the effect of broadening the Mg II emission by a further 30 Å or more.

Before leaving zone I we note that the expected ratio of the emission strength of Hβ to Mg II λ2798 for such a zone is about 1 : 5 (ref. 3). It should be noted that in the calculation by Osterbrock and Parker, Mg^+/total Mg is assumed to be 1/5, and a ratio of line strengths Mg II λ2798/Hβ ≈ 1 is obtained. In the present case effectively the whole of the Mg exists as Mg^+ in zone I. Since the strength of Hβ is about twice Mg II λ2798 in both 3*C* 273 and 3*C* 48, it is clear that in at least some quasi-stellar objects most of the emission in the Balmer lines does not come from zone I.

Passing to zone II, we note that the most abundant stages of ionization of the common elements are: H^+ He^+, He^{++}, C^{+3}, N^{+3}, $O^{++} \rightarrow O^{+3}$, Ne^{++}, Mg^{++}, Si^{+4}, S^{+4} Ar^{+3}. If we restrict ourselves to ground-state transitions and to the excitation of levels requiring only moderate energies, the possible emission lines are: hydrogen recombination (Ly-α, Hα and the Balmer series), helium recombination (λλ 1640, 3204, - - -), C IV (λλ 1548, 1551), N IV (none), O III (λλ 4363, 4959, 5007), O IV (λλ 1402, 1405, 1406, 1410, 1413), Ne III (λλ 1794, 1815, 3344, 3869, 3968), Mg III (none), Si V (none), S V (none), Ar IV (λλ 2854, 2869).

All these lines are seen in quasi-stellar objects, except for the weak lines of Ne III at λλ 1794, 1815, 3344. These

are weak because their electronic excitation probabilities are very small[7]. Plainly the gaseous material of quasi-stellar objects is very largely in zone II. This is the region that contributes mainly to the emission lines. Actually the He II λλ 1640, 3204 lines are weak, a fact that caused Osterbrock and Parker[3] some surprise, so that they wondered whether helium might be low in abundance. But they arbitrarily assumed a degree of ionization such that half the helium was He^{++}; in our model there is not much He^{++} because zone II is optically thick for $h\nu > 54{\cdot}403$ eV.

We have given the ionization state of oxygen as $O^{++} \rightarrow O^{+3}$. If all the O^{++} were in the ground state, most of the oxygen would be in this particular ionization stage, since the ionization potential of O^{++} is 54·886 eV, slightly above the ionization potential of He^{+}. However, O^{++} has metastable states several volts above the ground state, so that O^{++} can be excited in two stages, first to a metastable state, then to O^{+3} through the absorption of a quantum with $h\nu$ less than the ionization potential of He^{+}. Provided the metastable states of O^{++} become sufficiently populated most of the oxygen will be converted to O^{+3}. This we believe must be the situation in quasi-stellar objects, otherwise the lines of O^{++} would be somewhat stronger than C IV λλ 1548, 1551 (ref. 3).

The most abundant ionization stages in zone III are: H^{+}, He, He^{+}, $C^{+} \rightarrow C^{++}$, O^{+}, Ne^{+}, Mg^{++}, Si^{++}, S^{++}, Ar^{+}. The corresponding expected emission lines are: H I (Ly-α, Hα - - -), He I (λλ 2830, 2946, 3189, 3447, - - -), C II (λλ 1335, 2325), C III (λ1909), O II (λ3727), Ne II (none), Mg III (none), Si III (λ1206), S III (λλ 1190, 1194, 1201, 1202), Ar II (none). Accepting that the lines of Si III, S III may be blended with the wide Ly-α, the only lines which would be expected to be strong, but which are in fact found only weakly or not at all, are C II (λλ 1335, 2325). These omissions are probably to be explained by the proximity of the ionization potential of C^{+}, 24·376 eV, to that of He, 24·581 eV, and to the fact that C^{+} has a metastable state nearly 5 V above ground-level. With the latter sufficiently populated, C^{+} will be scoured out to C^{++}. The situation here for $C^{+} \rightarrow C^{++}$ is the same as it was for $O^{++} \rightarrow O^{+++}$ in zone II.

The line He I λ2830 may be present in some quasi-stellar objects. An evanescent line at this wave-length has been observed in 3*C* 345 by Burbidge and Burbidge[8]. This line may also be present in 3*C* 215 (ref. 9). The other members of the same series, λλ 2946, 3189, 3447, - - - have not been observed, however.

The zones I, II and III explain the emission lines of quasi-stellar objects quite satisfactorily. A few cases, probably peculiarities, requiring either exceptionally high electron temperatures or an optically thin situation beyond $h\nu = 54{\cdot}403$ eV, remain to be explained, particularly Ne V (λλ 2974, 3346, 3426) in emission, N V λ1240 in absorption in 3*C* 191, and a suspected emission line [Mg V] λ2931 in four objects. Leaving these cases aside, the next step is to decide on the spatial ordering of zones I, II, III.

We suggest the ordering I, II, III with increasing distance from a central object. At first sight we might expect zone I to lie on the outside. But this zone cannot cover zones II and III, otherwise Ly-α could never appear free of strong self-absorption. If zone I lies on the outside its structure must be broken into discrete blobs. The disadvantage of placing I on the outside is that, if Mg II λ2798 arises in it, the great widths shown by that line in some cases would then be hard to explain. With zone I on the inside, light from it must pass through zones II and III. If either zone II or zone III, preferably zone II, has $\tau_e \approx 1$ and $T_e \geqslant 30{,}000°$ K, the Mg II doublet will be substantially widened, to the widths observed in 3*C* 279, *MSH* 03–19, 3*C* 261, 3*C* 286 and *MSH* 14–121. The strong ultra-violet radiation field necessary to produce zone II must then arise outside zone I, by processes discussed elsewhere[10]. If Mg II λ2798 is produced by recombination, zone I is not necessary, and the line must undergo the same electron scattering as Ly-α and C IV λ1549.

We place zone III on the outside because the line [O II] 3727 is emitted most effectively at low densities. Our expectation is that the lowest electron densities are to be found on the outside of the object. Moreover, zone III must contain concentrations of C^{+}, Si^{+}, S^{+} which, while not sufficient to produce an emission line, may be sufficient in some cases to produce absorption, but all the Mg must here be in the form of Mg^{++} or an absorption component in Mg II λ2798 would be produced by Mg^{+}. In the foregoing discussion we have been concerned with the most abundant ionization stage. A not negligible number of ions that differ one stage, up or down, from the most abundant ion are always to be expected. In zone III we expect moderate concentrations of Si^{+} and Si^{+3}. Both these ions are responsible for absorption lines in 3*C* 191. To give a deep absorption it is therefore important that zone III should cover the whole source of the continuum, and this it will do best if it lies outermost from the source of the continuum.

Our picture is shown schematically in Fig. 1. The structure of the system has some similarity to a planetary nebula. The central hole is to be considered as maintained by radiation pressure from a central highly condensed object. The origin of the continuum flux arising in this central region has been discussed elsewhere[10]. Zone II is the main region of emission of lines. In some cases the optical depth τ_e is of order unity in this zone. It is of some interest to calculate the total flux which can be emitted from this region.

Estimates of Flux emitted from a 'Standard' Quasi-stellar Object

The condition that the optical depth for electron scattering $\tau_e \leqslant 1$, which will in general explain the widths of the lines in this model, enables us to compute the total optical emission from a 'standard' quasi-stellar object. Taking $T_e = 30{,}000°$ K in zone II, the number of electron-proton recombinations is $\sim 2 \times 10^{-13} N_e^2$, and the emissivity in Ly-α, Hα, etc., and in the Balmer continuum is $\sim 4 \times 10^{-24} N_e^2$ erg/cm³/sec. Thus the total emission from zone II in Ly-α, Hα, etc., is $\sim 10^{-23} N_e^2 R^3$ erg/sec.

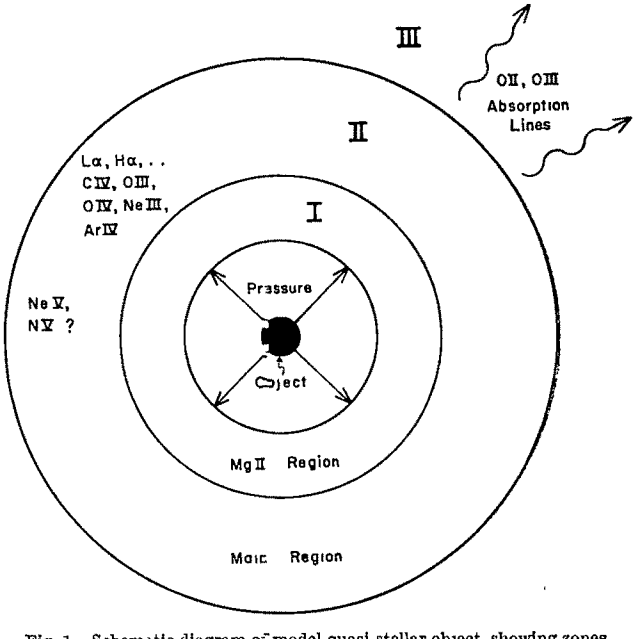

Fig. 1. Schematic diagram of model quasi-stellar object, showing zones I, II, and III

Since the total optical output is about ten times greater than the total hydrogen emission we obtain $\approx 10^{26} R$ ergs/sec for the total output when we set $N_e R \approx 10^{24}/\text{cm}^2$. The size R can be set by the optical and radio fluctuation data which give values of $R < 10^{17}$–10^{18} cm for objects such as 3C 345 and 3C 273. Thus the total energy output can only be of order 10^{43}–10^{44} ergs/sec, and the lower value is close to the luminosities of the Seyfert nuclei.

This result applies to the "standard" model. However, for the case of 3C 273 where there is a measured flux for Hβ it is interesting to derive similar quantities using Hβ alone. For $T_e = 30{,}000°$ K the volume emissivity:

$$E(H\beta) = 10^{-26} N_e^2 \text{ ergs/cm}^3 \quad (1)$$

Equating this to the measured flux, we find that if R is the dimension of the emitting region, $\Delta R = xR$ is the thickness of the shell, and r is the distance of the object:

$$\frac{N_e^2 x R^3}{r^2} = 3{\cdot}4 \times 10^{14} \quad (2)$$

If $N_e x R$ were appreciably greater than $\sim 10^{24}$, the resonance lines would become too broad. Thus we take:

$$N_e x R = 10^{24} \quad (3)$$

Substituting (3) in (2) we find that:

$$\frac{x r^2}{R} \approx 3 \times 10^{33}$$

For the object to be at the distance determined by its red shift, $r \approx 1{\cdot}5 \times 10^{27}$ cm, in which case $R = 7 \times 10^{20} x$. Taking three different values for R, we find:

(*a*) for $R = 10^{17}$ cm, $x = 1/7000$, and $N_e = 7 \times 10^{10}$;

(*b*) for $R = 10^{18}$ cm, $x = 1/700$, and $N_e = 7 \times 10^{8}$;

(*c*) for $R = 10^{19}$ cm, $x = 1/70$, and $N_e = 7 \times 10^{6}$.

These values of N_e are lower limits, since equation (3) is a limit for $\tau_e \leqslant 1$. A value for R as large as 10^{19} cm is probably excluded by the fluctuation data, and the electron densities for (*a*) and (*b*) are orders of magnitude greater than Greenstein and Schmidt's estimates and are incompatible with the observations. Only by making r smaller, apparently, and assuming the object is 'local' can this dilemma be avoided. For example, if we suppose that zone II can be approximated to by a sphere of radius R, and put $N_e R \approx 10^{24}$, then if $r = 5$ Mpc $\approx 1{\cdot}5 \times 10^{25}$ cm, we find: $R = 10^{33} r^2 = 2 \times 10^{17}$ cm, and $N_e = 5 \times 10^6$ cm^{-3}.

The scheme described here is a general one, and clearly the range of widths of emission lines seen requires a range in N_e, T_e and τ_e in the objects. In quasi-stellar objects where [O II] λ3727 is quite strong and wide, N_e may be lower and the line may be produced deeper in the object. Further, expansion motions may occur in some of the objects. We have sought here to reconcile the line fluxes and widths, and the electron densities, and to take account of electron scattering which has hitherto been set aside as unimportant. We have sought also to account for the appearance in some objects of absorption components in resonance lines, and in others not, and to explain why strong absorption in Ly-α and C IV λ1549 is not visible in all quasi-stellar objects and why absorption in the Mg II doublet has not been found in any such objects. In 3C 191, where absorption lines appear, the comparative weakness of absorption in Ly-α relative to absorption in C IV λ1549 can also be accounted for by the fact that H is largely ionized in zone III.

Clearly a range in the physical parameters of the emitting gas must be present in the quasi-stellar objects. One advantage of this model is that the arrangement and maintenance of the zones could be quite sensitive to the size and continuum flux of the central source of energy, about which we have not attempted to say anything here.

A CONSISTENT NOMENCLATURE FOR THE NUCLEAR STATUS OF FUNGAL CELLS

By PROF. J. L. JINKS and DR. G. SIMCHEN
Department of Genetics, University of Birmingham

WITH the rapid increase in cytological and genetical investigations of fungi, many terms that were originally introduced to describe morphological and physiological aspects of the life cycle have acquired new and often imprecise cytogenetical meanings. Other terms that were originally introduced to describe the cytogenetics of higher organisms have been applied to fungi without sufficient regard to the differences in level of organization[1,2]. The result is unnecessary ambiguity and loss of information. In this article we will examine the situation as it relates to the present-day nomenclature for the nuclear status of fungal cells in an attempt to arrive at a consistent terminology. We will begin with our proposals for a terminology which is essentially an extension of that used by Catcheside[3] and Olive[4].

Categories of Nuclear Status

We can recognize two major categories corresponding with two levels of organizations, namely (i) nuclei within cells and (ii) chromosomes within nuclei, both of which provide a basis of a nomenclature.

Within each of these categories we can recognize differences which are basically numerical (*a*), and differences which are primarily related to gene content (*b*).

(i) *a*. Any cell, spore or mycelium can be classified on the basis of the number of nuclei it contains, for example, uninucleate, binucleate or multinucleate. Equally, a uninucleate cell or spore or a mycelium made up of predominantly uninucleate cells can be referred to as a monokaryon. Similarly, a binucleate cell or spore or a mycelium made up of predominantly binucleate cells is a dikaryon. This

nomenclature can be extended to any number of nuclei per cell, so that for three nuclei, for example, the appropriate terms would be trinucleate and trikaryon. However, with more than two nuclei to a cell the number is usually indeterminate, since it varies from cell to cell in the same mycelium. Above two, therefore, the terms multinucleate, multikaryon (or coenocyte) are as precise as the situation justifies. These terms, of course, imply nothing about the gene content or ploidy of the nuclei themselves.

(i) *b*. In a comparable way, any cell, spore or mycelium can be classified on the gene content of the nuclei it contains. Irrespective of the number of nuclei involved, if they are all genetically identical, the cell, spore or mycelium is a homokaryon. On the other hand, if two or more genetically different types of nuclei are present, the cell, spore or mycelium is a heterokaryon.

(ii) *a*. The numerical status of the chromosomes within a single nucleus provides a basis for classification that is common to all organisms and presents no special difficulties when applied to fungi. Thus haploid, diploid, triploid and polyploid chromosome complements can be recognized as can aneuploid, disomic, trisomic and polysomic complements.

(ii) *b*. At the level of gene content the situation can be simply described in terms of the familiar homozygote and heterozygote.

Essentially, therefore, our terminology distinguishes between the properties of chromosome complements which are associated in the same nucleus and those which are associated in different nuclei within a common cytoplasm. The importance of this distinction is underlined by the results of investigations of the action and interaction of the same genes when associated in these different ways[5,6].

Combination of Categories: Redundancies and Misuses

The four subdivisions which we have recognized as a basis of classification are largely independent since they are describing events at different levels. They can, therefore, be combined in all possible combinations to provide a comprehensive description of any situation that may arise. There are, however, some combinations in which one term is redundant. An example of this is the term homozygous when used in conjunction with haploid (since a haploid nucleus cannot be heterozygous), but this is the only case in which this is invariably so.

A combination that appears at first sight to have redundancies is haploid homokaryotic monokaryon. If this refers to a single cell or a spore, then haploid monokaryon is a sufficient description since all monokaryotic single cells or spores are homokaryotic. On the other hand, not all monokaryons are homokaryotic, and not all homokaryons are monokaryotic. For example, if we are referring to a mycelium, no term in the description haploid homokaryotic monokaryon is necessarily redundant since a haploid monokaryotic mycelium can be heterokaryotic[7] and a haploid homokaryon can be a multikaryon (as, for example, in *Aspergillus* and *Neurospora*).

A common assumption that is implicit in present-day usage is that monokaryon can mean either one nucleus per cell, or one kind of nucleus per cell (homokaryon), or both simultaneously. Dikaryon in the same way can mean either two nuclei per cell, or two kinds of nuclei per cell (heterokaryon), or both simultaneously. A further misuse is to equate dikaryon and heterokaryotic dikaryon[8]. As a consequence, dikaryon cannot be used to describe the binucleate stage which precedes nuclear fusion in the sexual stage of homothallic Ascomycetes and Basidiomycetes even though this stage is clearly evolutionarily equivalent to the morphologically similar stage in heterothallic species[9,10]. Equally confusing is the use of dikaryon and trikaryon for the heterokaryotic association of two and three distinct types of nuclei in the multinucleate, vegetative hyphae of heterothallic Ascomycetes such as *Neurospora crassa* where such associations are confined to strains of the same mating type[11]. These misuses of the term dikaryon are analogous to confining the use of the term diploid to heterozygotes only, but extending its use to any degree of ploidy.

In an attempt to avoid ambiguity some have referred to dikaryons as either homozygous or heterozygous[12,13]. This, however, is also wrong, since it is applying terms to the wrong level of organization. The correct terms are homokaryotic dikaryon and heterokaryotic dikaryon which free the terms homozygous and heterozygous to describe the constitution of the individual nuclei. Even more confusing is the use of haploid and diploid to describe monokaryotic and dikaryotic cells respectively[1]. Now that homozygous and heterozygous diploid nuclei can be produced in fungi by a variety of procedures, strains which are heterozygous diploid homokaryotic dikaryons or homozygous diploid heterokaryotic dikaryons are a possibility. Indeed, in *Coprinus*, haploid and heterozygous diploid nuclei have been associated in a dikaryon to produce a haploid/heterozygous diploid heterokaryotic dikaryon[14]. Only by strict adherence to the terminology proposed here, in which each term is used to specify the correct level of organization, can we hope to describe unambiguously all the situations that have already arisen or that are likely to arise in the future.

Justification and Uses

The proposed terminology clearly satisfies the requirement that it should provide a classification of the nuclear status of fungal spores and cells that brings out the more readily observable similarities and differences. But are these similarities and differences biologically meaningful?

One of the most important proposals in this terminology is that homokaryon and heterokaryon should be used where appropriate in conjunction with monokaryon, dikaryon or multikaryon to describe the vegetative and reproductive cells and the spores of fungi. Heterokaryosis of the type with which we are familiar in imperfect fungi, in homothallic Ascomycetes and within a mating type of heterothallic Ascomycetes is essentially a system of vegetative plasticity[15]. In these fungi, a heterokaryotic association arises solely because of its immediate advantage in vegetative growth over its homokaryotic components and it persists only so long as this advantage is maintained. The longer-term advantages of heterokaryosis, for example, the possibility of outcrossing in homothallic fungi and of parasexual recombination in imperfect and sexual fungi, are only secondary consequences of heterokaryon formation[16]. The success or failure of the new genotypes that may arise in these ways plays no direct part in the success or failure of heterokaryon formation when two homokaryotic strains meet.

Dikaryon formation of the type that is known in heterothallic Ascomycetes and Basidiomycetes is an essential first step in sexual reproduction. And even where, as in many Basidiomycetes, the dikaryotic stage is capable of prolonged and independent vegetative growth before the production of sexual spores, the formation of the heterokaryotic dikaryon does not depend on any immediate advantage in vegetative vigour. On the contrary, stable dikaryons are formed between monokaryons providing that they are sexually compatible even when the heterokaryotic dikaryon has a rate of growth that is inferior to one or both of its component monokaryons[13,17]. Indeed, in some instances, most of the dikaryons produced by random pairing of compatible monokaryons obtained from fruiting bodies growing in the wild may be inferior in rate of growth to one or both component monokaryons. Further investigations of the genetical determination of the vegetative characteristics of dikaryons obtained from the wild suggest that these characters are subjected to

stabilizing selection which favours intermediate performance[17]. Clearly, the formation and persistence of a heterokaryotic dikaryon do not depend on an increase in vigour arising from the heterokaryotic association but rather on the advantages that result from sexual outcrossing of which this association is the first and most important step. Heterokaryotic associations thus appear to be of two markedly different kinds that have evolved to fulfil different and independent roles and as such are subject to different selective forces[18]. We can justify the use of heterokaryon for both only if we are using the term descriptively, implying no evolutionary or functional relationship. Even so, this is preferable to the alternatives at present in use, such as heterozygous dikaryon and the restriction of the term dikaryon to heterothallic species, since these not only imply incorrect relationships and differences but are also incorrect descriptions of the nuclear status.

To give a complete description of the nuclear status of every kind of cell, spore or mycelium using the terminology we have proposed would be tedious and is frequently unnecessary. On the other hand, even such a complete description is considerably briefer, less circuitous and more informative than many of the descriptions that are to be found in the literature. However, we suggest that, in general, our terminology should act merely as a guide to the correct description, and should be fully applied only to an unusual situation or to a formerly unknown nuclear condition (for the particular fungus concerned). Our system will tolerate the use of any term which is unambiguous for the group of organisms to which it applies, and which does not break the rules of our terminology, for example, by applying the term to an incorrect level of organization. Thus, for the filamentous Ascomycetes, the homokaryon–heterokaryotic notation for mycelia will usually be adequate since it is known that the growing points of the mycelia are usually multikaryotic and all the nuclei normally haploid. Similarly, for the heterothallic Basidiomycetes, the monokaryon–dikaryon notation will suffice as a description since the former is usually haploid and homokaryotic and the latter is haploid and heterokaryotic, at least for the incompatibility factors. (Yeasts, on the other hand, could be described as haploid or diploid for most purposes since they usually contain only one nucleus per cell, although care should be taken in referring to the breeding system.)

The purpose of the terminology developed here is clearly not to confuse or to add an unnecessary complication to the notations at present in use. On the contrary, we hope to achieve clarification of the different terms and to develop and generalize the terminology so that it will unambiguously cover all nuclear stages in the fungi.

This work was supported by a grant from the Agricultural Research Council of Great Britain.

RECOLLECTIONS OF LORD RUTHERFORD*

By Academician P. L. KAPITZA

THE only way in which I can satisfy the interest of the members of the Royal Society is to speak of Rutherford the man, of how I remember him during my 13 years' work in the Cavendish Laboratory, of how he worked, how he trained us young scientists and also of his relations with the scientific world. My task is therefore to draw you a portrait of a great scientist and of a great man. Frankly, this is the job of a writer and not of a scientist. If I have now decided to do so, this is mainly for the following reasons. When I look back and see myself as a young man coming to England in 1921 and starting work in the Cavendish Laboratory and, after 13 years, growing into a scientist, I feel that these years of my work were the happiest, and for all my achievements I feel immensely grateful for the attention and kindness which Rutherford showed me, not only as a teacher but as a very kind and sympathetic man for whom I have a sincere affection and with whom I eventually became great friends.

I would like to begin with a small episode which happened in 1930 in the Cavendish Laboratory. At that time a small conference was being held in Cambridge to commemorate the centenary of the birth of Maxwell, the first director of the Cavendish Laboratory. After the official part of the meeting in which some of Maxwell's pupils talked of their reminiscences, Rutherford asked me how I liked the speeches. I answered that they were very interesting, but I was surprised that all the speakers spoke only of the positive side of Maxwell's work and personality and made a "sugary extract" (*sic*) of him, and I said that I would like to see Maxwell presented as a living figure with all his human traits and faults which, of course, every man possesses however great his genius. Rutherford as usual laughed and said that he charged me after his death to tell future generations what he was really like. He was joking and I was laughing too. And now when I try to fulfil his behest and I imagine Rutherford as I have to present him before you, I see that time has absorbed all his minor human imperfections and I can only see a great man with an astounding brain and great human qualities. How well I now understand Maxwell's pupils who spoke about him in Cambridge.

In science, as in history, definite stages of development demand their particular kind of genius. A definite period of development requires men with corresponding mental abilities. In the history of the development of physics, as in any other experimental science, the most interesting periods are those in which we are brought to revise our fundamental scientific conceptions. Then not only deep thinking and intuition are required from the scientist but also a daring imagination.

The peculiar character of Rutherford's thinking could easily be followed when talking to him on scientific topics. He liked being told about new experiments, but you could easily and immediately see by his expression whether he was listening with interest or whether he was

The Biological Significance of Climatic Changes in Britain

Institute of Biology Symposia Number 14

edited by **C. G. Johnson** and **L. P. Smith**

With the advent of long-term weather forecasting farming operations may well be approached with more knowledge than formerly of what the seasons are going to be like. This book discusses the problems that may be involved and the possible uses of long-term weather forecasts from season to season within a general context of very slowly changing climate over the years.

1965, 222 pp., 42s.

Biochemistry of the Retina

edited by **Clive N. Graymore**

This volume based on the Proceedings of the first International Symposium on the Biochemistry of the Retina collates both current and review aspects of the major topics of interest in retinal biochemistry. It is intended that this volume should be the first of many that will provide future investigators both in this and allied fields with a continuous and informative literature.

1965, 172 pp., 60s.

Generalized Functions

VOLUME 5: INTEGRAL GEOMETRY AND REPRESENTATION THEORY

by **I. M. Gel'fand, M. I. Graev,** and **N. Ya. Vilenkin**

Translated from the Russian edition

Discusses the Radon and other integral transforms on real and complex spaces. It then treats S(2,C) and the representations and harmonic analysis of this group. Particular attention is given to the representations of S(2,R).

November 1966, about 625 pp., approx. 148s.

Algebraic Linguistics: Analytical Models

by **Solomon Marcus**

Presents some theoretical problems in the field of mathematical linguistics, through the use of analytical models. It contains sections on languages and partitions, linguistic typology, parts of speech and syntactic types, grammatical gender, configurations and subordination and projectivity.

September 1966, about 225 pp., approx. 76s.

SECOND EDITION

Solution of Equations and Systems of Equations

by **Alexander M. Ostrowski**

Thoroughly revised with much new material added, this book considers methods of numerical solution of equations; first, a single equation in one unknown, and then systems of equations with a corresponding number of unknowns.

September 1966, about 350 pp., 94s. 9d.

SIGNIFICANT

PERGAMON PUBLICATIONS

PROGRESS IN NUCLEAR ENERGY SERIES X

Law and Administration Volume 4

Edited by **J. L. Weinstein,** *formerly O.E.E.C. European Nuclear Energy Agency*

Unlike previous volumes in this series this book is not devoted exclusively to the topic of nuclear liability though it remains within the broad framework of law and administration in nuclear energy.

Partial Contents: The Vienna International conference on civil liability for nuclear damage; The Paris supplementary convention; International conventions on civil liability and Latin American legislations; Liability legislation in Japan; Some factors influencing the regulation of nuclear health and safety.

368 pages **May 1966** **£5/$15.00**

HEAT AND MASS TRANSFER IN CAPILLARY-POROUS BODIES

A. V. Luikov, *Heat and Mass Transfer Institute, Minsk*

Gives a description of the modern theory of heat and mass transfer on the basis of the thermodynamics of irreversible processes with a systematic account of the phenomena of heat and mass transfer in capillary-porous bodies.

Contents: Thermodynamics of the phenomena of heat and mass transfer; Equations of mass and heat transfer and conditions of single-valuedness; Fundamentals of the theory of similarity; Heat and mass transfer of a solid body with the surrounding medium; Basic properties of capillary-porous bodies; Heat and mass transfer in capillary-porous bodies; Heat and mass transfer in walls; Heat and mass transfer in some engineering processes; Experimental methods of investigation; Methods of numerical solution; Appendices; Bibliography; Index.

536 pages **March 1966** **£6 10s/$20.00**

RADIO REMOTE-CONTROL AND TELEMETRY AND THEIR APPLICATIONS TO MISSILES

J. Marcus

This book constitutes a comprehensive survey of theoretical and practical advances in remote control and telemetry with special reference to missiles, and provides a well-documented account of the achievements and problems facing missile engineers and designers.

Contents: General remarks; The different types of modulation; Information and coding; Limitations on information; Field propagation and aerials on missiles; Radio links for remote control and telemetry equipment, regarded as multiplex systems; Radio telemetry equipment; Conclusion; Bibliography; Index.

272 pages **May 1966** **70s/$11.50**

PROGRESS IN BIOPHYSICS AND MOLECULAR BIOLOGY—Volume 16

Edited by **J. A. V. Butler,** *Chester Beatty Research Institute, Royal Cancer Hospital and* **H. E. Huxley,** *University Postgraduate Medical School, Cambridge*

These volumes contain a representative series of articles on a variety of topics that illustrate the wide range of knowledge which can be considered as coming within the field of biophysics and molecular biology. Volume 16 continues the process of building a cumulative picture of this field.

Contents: Recognition of antigen by cells; Genetic transcription or DNA-dependent RNA synthesis; Cybernetic interactions in epigenetics; The organization and function of the sarcoplasmic reticulum and T-system of muscle cells; The molecular organization of cell membranes; Progress in high-resolution autoradiography; Molecular genetics of bacteria and bacteriophages; Electrophoretic behaviour of cells.

BIORHEOLOGY

Editors in-Chief **A. L. Copley** and **G. W. Scott Blair**

Biorheology comprises the study of deformation and flow of biological systems of materials directly derived from living organisms. Such problems have recently assumed an increasing importance in physiology and medicine, botany and other biological disciplines. This journal publishes work in English, French and German concerned with process in the living organism. Published Quarterly.

bored. You had to talk only about fundamental facts and ideas without going into the technical details in which Rutherford took no interest. He grasped the basic idea of an experiment extremely quickly.

When I came to Cambridge, Rutherford was no longer doing experimental work by himself; he worked chiefly either with Chadwick or with Ellis. But in both cases he took an active part in experiments. The most attractive thing about Rutherford's experiments was the clear way in which the problem was set out. The simplicity and directness of approach to the solution of the problem were most remarkable.

I did not work with Rutherford, as my investigations were not connected with nuclear physics, and therefore I did not see him working in his laboratory. But I know that up to the very end of his life the main bulk of his time was taken up by his personal scientific research. The detailed guidance of scientific work he left to one of the senior scientific workers, usually Chadwick. But he himself always took an interest in the choice of the problem for experiment and of the experimental approach. He often came to the laboratory, but only for a short time just to make remarks like: "Why don't you get a move on—when are you going to get some results?" When I started working in the Cavendish Laboratory such remarks made a deep impression on me, especially as they were made in a thundering voice and with a severe expression. But eventually I found out that such utterances were automatic, maybe customary for a New Zealand farmer who when going through the fields found it useful to stimulate the workers with a few 'kind' words.

The greatest quality of Rutherford as a teacher was his ability to conduct research work in the right direction, then to encourage the beginner and to give just appraisal of his achievements. What he valued most in a pupil was independent thought and originality in his work. Rutherford did his utmost to develop in his pupil an individuality. I remember how in the first years of my work in the Cavendish I once said to Rutherford: "You know that the work of X is pretty hopeless; don't you think he's wasting his time and apparatus?" Rutherford replied that he too knew that the man was working on a hopeless problem. "But," he said, "it is a problem of his own and even if the work cannot be accomplished it will lead him to another original research problem which will be successful." The future showed that Rutherford was right.

Rutherford was very particular to give credit for the exact authorship of any idea. He always did this in his lectures as well as in his published works. He was also very particular not to give a beginner technically difficult research work. He reckoned that, even if a man was able, he needed some success to begin with, otherwise he might be disappointed in his abilities which could be disastrous for his future. Once, in one of our outspoken talks, he told me that the most important thing a teacher must learn is not to be jealous of the successes of his pupils—which is not so easily done as the teacher gets older! No doubt the greatest quality of a good teacher should be generosity. Rutherford was undoubtedly very generous and I think this is one of the main secrets which explains why so many first-class scientists came from his laboratory. He well understood the importance that his pupils had for him. It was not merely that young research students increased the scientific productivity of the laboratory, but, as he said, "My pupils keep me young". This is very true, as pupils do not permit a teacher to lag behind new achievements in science. Rutherford, with great ease and generosity, always accepted new ideas in physics like wave quantum mechanics, while a number of distinguished scientists of his generation were sceptical of the same ideas. He was very sociable and loved talking to the scientists who came to visit him and the Cavendish Laboratory. I remember one occasion when he brought Prof. Robert Millikan to my room in the laboratory. Rutherford said to me, "Let me introduce you to Millikan; no doubt you know who he is. Show him your installation to produce strong magnetic fields and tell him about your experiments. But I doubt whether he will let you speak as he himself will tell you about his own experiments!" There followed loud laughter in which Millikan joined with rather less enthusiasm. Rutherford then left us, and I soon found out that his prophecy was correct.

Later on, when I became a Fellow of Trinity and used to accompany him home after dinner on Sundays, we often discussed politics. On the first day I started work in the Cavendish I was surprised to hear him saying to me that in no circumstances would he tolerate my making Communist propaganda in his laboratory. At the time this remark came quite unexpectedly. It not only surprised me, but also shocked me and to a certain extent even offended me. Undoubtedly it was a consequence of the current atmosphere of acute political struggle and was connected with the propaganda which existed in those days—only four years after the Russian revolution. Before coming to England, I was so absorbed by my research work in Russia that I was completely unaware of what was happening in Western Europe and could not appreciate the scale of the bitter political controversy which then existed. Later on when my first experimental research was published I presented Rutherford with a reprint and I made an inscription on it that this work was proof that I had come to his laboratory to do scientific work and not to make Communist propaganda. He became extremely angry with this inscription, swore and gave me the reprint back. I had foreseen this and I had another reprint in reserve with an extremely appropriate inscription with which I immediately presented him. Obviously Rutherford appreciated my foresight and the incident closed. Rutherford had a characteristically hot temper but cooled down just as quickly.

Eventually we had many conversations on political questions; we were especially concerned about the growth of fascism in Europe. Rutherford was an optimist and thought that all would soon be over. We now know that this was not the case. Rutherford, like most scientists who work in the exact sciences, had progressive political views. I involved Rutherford in some political activity on two occasions.

The first of these was connected with Langevin. In his younger days, Rutherford had worked with Langevin in the same room at the Cavendish. A deep friendship developed between them. In Paris, my friends, pupils of Langevin, were greatly shocked that Langevin, undoubtedly the best French physicist, had not been elected to the French Academy as a result of his left political views. I told Rutherford of the difficulties Langevin had encountered in France and asked him whether a man who held such leftist views as Langevin could be a foreign member of the Royal Society. Rutherford said something I could not quite follow, then started to tell me what a really good man Langevin was, and then recalled that during the First World War Langevin had been very active in inventing supersonic beams propagated in water by which he had established communications between England and France across the Channel. At this point the conversation ended. I learned later that at the next election in 1928 Langevin was elected a foreign member of the Royal Society and this was much earlier than his election to the French Academy.

The second example occurred much later, when Hitler started to come into power. We were very anxious about the fate of such distinguished physicists as Stern, Franck, Born and a number of others in the conditions of active and increasing anti-semitism in Germany. About this time Szilard came to England and we were faced with the question of how to get these scientists out of Germany without raising suspicion. I spoke to Rutherford and he was very willing to help, writing personal letters to these scientists, and inviting them to come to lecture in Cambridge.

The following will serve to demonstrate Rutherford's skill in handling complicated psychological problems. I think enough time has now passed that I can tell you about this case which involved the then well-known physicist, Paul Ehrenfest.

Ehrenfest was born in Austria. On one of his mountaineering excursions he met a Russian woman scientist and followed her to Russia where he married her. In Russia he published a number of outstanding theoretical works on thermodynamics. Eventually he was invited to Leiden University to take the chair of theoretical physics vacated by the great Lorentz. In Leiden, Ehrenfest and his house became one of the world centres of theoretical physics. Ehrenfest's main quality was his precise critical mind. He was not only a very good teacher of young scientists, who were very fond of him, but his criticisms were regarded as profound and of such high quality that leading theoretical scientists like Einstein and Bohr often came to Ehrenfest to discuss their work. Ehrenfest always noticed even the smallest contradiction or mistake. His critical remarks were made very readily, with great spirit and even sharply, but always very good-naturedly. The quality of his criticism was greatly appreciated.

Ehrenfest's exceptionally strong critical mind evidently acted as a restraint on his creative imagination and he did not succeed in producing scientific work which he himself would have considered of sufficiently high standard. In those days I did not know that in his acute nervous condition Ehrenfest suffered greatly when he could not in his work attain the level of the friends he criticized. In the beginning of 1934 I received a long letter from him in which he described in detail his state of mental depression and spoke of the futility of his achievements. He had come to the conclusion that it was not worth living any more. The only way to save himself, he thought, was to leave Leiden and settle somewhere away from his friends. He asked me to help him to find a chair at some small university in Canada and to ask Rutherford, who doubtless had connexions in Canada, to assist him. I was, of course, very upset by this letter. I handed Rutherford the letter and told him that we were very worried about Ehrenfest's future as, without any doubt, the letter showed that he was mentally unbalanced; perhaps, I said, this state was only temporary and everything possible should be done to help him out of his state of depression. Rutherford said I must not worry and he would handle the case himself. I do not know what Rutherford wrote to Ehrenfest, but shortly afterwards I received a letter telling me that he was once again in a happy frame of mind. He said that Rutherford had explained what a great part he was playing in physics and he added that of course there was now no need for him to go to Canada.

All this happened only a few months before I went to Russia, as usual, to see my mother and my friends and, unexpectedly for me, I was deprived of the possibility of returning to Cambridge. Then for some years I could not participate on the same scale as before in international scientific activities and my correspondence with Ehrenfest ceased. I subsequently learned that a year or two later his state of depression returned and he committed suicide.

Finally, I should like to discuss a question I have come across several times in descriptions of Rutherford's activities. The question is: did Rutherford foresee the great practical consequences which would emerge from his scientific discoveries and investigations into radioactivity?

The immense reserves of energy which are hidden in matter were understood by physicists a long time ago. The question which was not clear at that time was: would it eventually be possible to find technical means of making practical use of these reserves? We know now that the actual possibility of obtaining energy from nuclear collisions was becoming more and more real as nuclear phenomena were better understood. But up to the last moment it was not certain whether it would be technically possible to produce nuclear reactions with a great yield of energy. I remember only rare occasions on which I discussed this question with Rutherford, and in all these conversations he expressed no interest in it. I think that his opinions on the practical applications of nuclear physics had no real value, as they lay outside the scope of his interest and tastes.

The last time I saw Rutherford was in the autumn of 1934 when I went to the U.S.S.R. and was unable to return to Cambridge. For the next three years the only scientist with whom I freely corresponded outside Russia was Rutherford. In his letters he gave me an account of life in Cambridge, spoke about the scientific achievements of himself and his pupils, wrote about himself, made jokes, gave good advice and invariably cheered me up in my difficult position. He understood that the important thing for me was to start my scientific work which had been interrupted for several years. It is no secret that it was only due to his interference and help that I was able to obtain the scientific installation and apparatus of the Mond Laboratory, and in three years' time I was able to renew my work in the domain of low-temperature physics.

I am sure that in the course of time all Rutherford's letters will be published but even so I should like here and now to quote three short extracts which require no comment.

On November 21, 1935, he wrote:

". . . I am inclined to give you a little advice, even though it may not be necessary. I think it will be important for you to get down to work on the installation of the laboratory as soon as possible, and try and train your assistants to be useful. I think you will find many of your troubles will fall from you when you are hard at work again, and I am confident that your relations with the authorities will improve at once when they see that you are working whole-heartedly to get your show going. I would not worry too much about the attitude or opinions of individuals, provided they do not interfere with your work. I daresay you will think I do not understand the situation, but I am sure that chances of your happiness in the future depend on your keeping your nose to the grindstone in the laboratory. Too much introspection is bad for anybody! . . ."

On May 15, 1936, he wrote:

". . . This term I have been busier than I have ever been, but as you know my temper has improved during recent years, and I am not aware that anyone has suffered from it for the last few weeks!

". . . Get down to some research even though it may not be of an epoch-making kind as soon as you can and you will feel happier. The harder the work the less time you will have for other troubles. As you know, a reasonable number of fleas is good for a dog—but I expect you feel you have more than the average number!"

The last letter is dated October 9, 1937. He wrote in great detail about his proposed journey to India. In the last part of the letter he said:

". . . I am glad to say that I am feeling physically pretty fit, but I wish that life was not quite so strenuous in term-time. . . ." Ten days before his death he did not feel that it was so near.

For me the death of Rutherford meant not only the loss of a great teacher and friend; for me, as for a number of scientists, it was also the end of a whole epoch in science.

Obviously we should attribute to those years the beginning of the new period in the history of human culture which is now universally called the scientific-technical revolution. One of the greatest events in this revolution has been the use of atomic energy. In 1921 Rutherford warned me not to make any Communist propaganda in his laboratory, but it now appears that just at that time he himself together with his pupils were laying the foundations for a scientific-technical revolution.

But, nevertheless, the year that Rutherford died there disappeared for ever the happy days of free scientific work which gave us such delight in our youth. Science has lost her freedom. Science has become a productive force. She has become rich but she has become enslaved and part of her is veiled in secrecy.

I do not know whether Rutherford would continue nowadays to joke and laugh as he used to do.

NEWS AND VIEWS

Biochemistry in the University of Liverpool: Prof. R. A. Morton

PROF. R. A. MORTON will retire from the Johnston chair of biochemistry in the University of Liverpool at the end of the present session after 42 years of service on the university staff. Appointed lecturer in chemistry in 1924, he developed a keen interest in spectroscopy under the influence of Prof. E. C. Baly and became a pioneer in the application of absorption spectroscopy to the examination of complex substances of biological origin, particularly the fat-soluble vitamins. His achievement was recognized by the award of the Meldola Medal in 1930, and after a year as visiting professor in Ohio State University, he was appointed special lecturer in spectroscopy at Liverpool in 1931. In collaboration with a number of postgraduate students and visiting research Fellows he discovered vitamin A_2 and demonstrated that the retinal pigment, retinene, was the aldehyde of vitamin A. His experience in characterizing compounds by their absorption spectra was invaluable during the Second World War when he undertook a number of research projects for the Ministries of Food and Supply and participated in the Sheffield experiment organized by the Medical Research Council to determine vitamin A requirements with the aid of human volunteers. He was appointed to the Johnston chair of biochemistry in 1944, and at the end of the War quickly applied the newly developed Beckman photoelectric spectrophotometer to his researches. His valuable contributions to the chemistry and biochemistry of the fat-soluble vitamins, carotenoids and sterols were recognized by his election to a fellowship of the Royal Society in 1950. Although his interests in biological compounds had originally been chemical, he willingly served on a number of committees and panels concerned with the practical aspects of human nutrition. One of his major contributions to biochemistry, however, is evident in the number of former members of his Department who now hold senior appointments in industry and in universities throughout the world. In recent years he and his research group opened up new and widely developing fields of biochemical interests through the discovery of families of biologically active quinones and related compounds by chromatographic and spectrographic methods. These compounds have been found widely distributed in Nature and given the names ubiquinones, ubichromenols and dolichols. Investigations of their functions are still at an interesting but early stage of development.

Prof. Morton has lectured at many academic centres in Europe and the United States. In 1963, the University of Coimbra conferred on him the honorary degree of D.Sc., and recently the Biochemical Society elected him to honorary membership.

Prof. T. W. Goodwin

PROF. T. W. GOODWIN, professor of biochemistry and agricultural biochemistry at Aberystwyth, returns to Liverpool in October at the invitation of the University Council to occupy the Johnston chair of biochemistry, in succession to Prof. R. A. Morton. He was appointed to the chair of agricultural chemistry at the University College of Wales, Aberystwyth, in 1959, and he has developed a flourishing teaching and research school in biochemistry, recently accommodated in new laboratories. He is well known for his work on the carotenoids which developed out of his interest in visible and ultra-violet spectroscopy, and for his collaboration with Prof. R. A. Morton in work on vitamin A. His interests now extend into metabolic studies on all terpenoid materials in plant tissues, particularly in relation to the regulation of their formation in plant cells. He has also made considerable contributions in the field of thiamine and riboflavin biosynthesis. Prof. Goodwin has written a number of books, including *The Comparative Biochemistry of the Carotenoids*, *The Biosynthesis of Vitamins and Related Compounds* and *Recent Advances in Biochemistry*. He has also edited two volumes on *Biological Structure and Function* (with O. Lindberg), *Structure and Activity of Enzymes* (with J. I. Harris and B. S. Hartley), *The Chemistry and Biochemistry of Plant Pigments* and *Aspects of Insect Biochemistry*. Prof. Goodwin has lectured in several European countries and in Egypt, and last session he spent 6 months at the University of California, Davis, as senior foreign scientist Fellow of the National Science Foundation. He was director of a symposium sponsored by the North Atlantic Treaty Organization on the biochemistry of chloroplasts, which was held at Aberystwyth in 1965. He is a committee member of the Biochemical Society and is its symposium organizer and chairman of its Advisory Committee on Publications; he is also vice-president of the Comité International de Photobiologie.

New Directions of Comparative Zoology

ERNST MAYR, director of the Museum of Comparative Zoology and Alexander Agassiz professor of zoology at Harvard University, emphasized the 'gratifying rejuvenation' that systematics and evolutionary biology, the two branches most actively pursued at the Museum of Comparative Zoology, have undergone in the past few years. While the basic quest is still the same—"to investigate the diversity of the living world in order to understand the causes of this diversity"—Prof. Mayr said that field work to study the living organism in relation to its environment has become a necessary part of research. In addition to his traditional task of describing and naming new organisms, the taxonomist "increasingly studies behavior, distribution, niche occupation, population structure, environmental physiology, and all aspects of evolution". To facilitate this new emphasis on living organisms, the Museum is in the process of acquiring a field research station in Concord, Massachusetts, and is planning a new wing, largely devoted to the study of living animals.

Increasing teaching commitments of the scientific staff are also changing the Museum's traditional position as a research body. To meet the demand, new teaching facilities are being installed in the Museum and will be ready for the academic year 1966–67. Staff members for the first time are offering specialized seminars under Harvard's Freshman Seminar Programme. In addition, members are giving fifteen courses in the biology and geology departments.

Prospects for Biology

THE content and organization of degree courses in the biological sciences are undergoing considerable reappraisal.

Two significant, though not exclusive, lines of development are worthy of comment. First, degree courses in biology *per se* are being established in contrast to the traditional study of botany and zoology as separate disciplines. Such an approach places emphasis on the integration of plant and animal studies, on unitary concepts in biology and on a fuller appreciation of plant–animal interactions. Secondly, microbiology is coming to be recognized as a degree subject in its own right, no longer to be equated with medical bacteriology or other narrow specialist treatments. These two approaches have much in common, among the most important being their attempts to integrate and rationalize biology and to require its firm basis in the physical sciences.

Although the output of microbiology graduates from British universities and colleges is small, the present demands from industry and research laboratories are considerable and ever expanding. On his appointment to the newly created chair of microbiology in University College, Cardiff, Prof. D. E. Hughes has directed timely attention to this widening scope and importance of microbiology (*Microbes in Action*. An Inaugural Lecture delivered at University College, Cardiff, April 30, 1965. By Prof. D. E. Hughes. Pp. 21. Cardiff: University of Wales Press, 1965. 3*s*. 6*d*.). Apart from the more academic aims and achievements of contemporary microbiology, reference is made to the extension of industrial processes, based on the activities of micro-organisms, and to the technological exigencies imposed by such operations. Prof. Hughes's inaugural address presents a broad survey of microbiology and gives heed to its further advance, exploitation and some possible consequences of its neglect. It is to be hoped that the training of graduates in this field will keep pace with the requirements of industry and elsewhere and that disparity in present supply and demand will be redressed. The time is opportune for a careful assessment of the types of biologist Britain needs and will continue to need in the approaching decade; the recent misjudgment of the number of medically qualified graduates required is a cogent argument for such an enquiry.

Royal Society/Royal Geographical Society Expedition to Mid-West Brazil

THE Royal Society and the Royal Geographical Society are considering jointly sponsoring scientific investigations in the little-known interior of Mato Grosso in mid-west Brazil. A reconnaissance party of three is now on its way for a two-month visit to discuss with Brazilian scientists and officials plans for a larger expedition from Britain, possibly next year.

The leader of the reconnaissance party is Mr. A. F. MacKenzie, a tropical plant ecologist, and he will be accompanied by Mr. I. R. Bishop, a zoologist from the University of Leicester, and Mr. D. R. Hunt, a botanist from the Royal Botanic Gardens, Kew. Mr. MacKenzie sailed for Rio de Janeiro in mid-April, with the reconnaissance party's supplies, and will be followed shortly by Messrs. Bishop and Hunt.

Lasers for Teaching

THE laser is now an accepted new light source for use both in teaching laboratories and in scientific and technological research. Though specifically related to the demountable continuous gas laser produced by Scientifica and Cook Electronics, Ltd., the manual entitled *The Gas Laser and its Experimental Applications*, by R. J. Horton and P. D. Cook, is a valuable and easily understood guide to various experiments which can be used for teaching and demonstration purposes using a helium–neon gas laser (Pp. 31. London: Scientifica and Cook Electronics, Ltd., 1965. 12*s*. 6*d*.). Detailed instructions are given for alignment and operation of the laser, in addition to the precautions necessary while handling the source. A clear introductory statement describes the theory of the laser, and the various cavity arrangements and the dependence of action of the laser on them. The experiments chosen as examples consist of the demonstration of lens aberrations, Fraunhofer diffraction and interference patterns, Fourier transforms, the Michelson interferometer, and the Abbé theory of image formation.

Root Rot of Teak

DR. B. K. BAKSHI, of the Forest Research Institute, Dehra Dun, India, has written to the Editor reporting an outbreak of root rot diseases of teak (*Tectona grandis* Linn. f.). The outbreak occurred in a plantation at the demonstration forest attached to the Institute (the plantation was established in 1928 and coppiced during 1945): "Two pathogens were encountered, namely, *Polyporus zonalis* Berk., and a species of *Peniophora*. The decay in the roots has resulted in wind throw of trees. So far as I can ascertain, *Peniophora* has not previously been recorded in teak. It colonizes old coppiced stumps and spreads freely through the soil by means of yellow rhizomorphs which infect healthy roots, in which a yellow spongy or yellow laminated decay develops. Sporophores are common. The fungus has not been encountered before".

Geological Society of London

AT the annual general meeting of the Geological Society of London on April 27 the officers and Council for the ensuing year were elected as follows: *President*, Prof. K. C. Dunham, University of Durham; *Secretaries*, W. B. Harland, University of Cambridge; Prof. J. Sutton, Imperial College of Science and Technology; *Foreign Secretary*, Prof. O. M. B. Bulman, University of Cambridge; *Treasurer*, Dr. W. Bullerwell, Geological Survey and Museum.

U.S. National Academy of Sciences

DR. H. BROWN, professor of geochemistry at the California Institute of Technology, has been elected to a second four-year term as foreign secretary of the U.S. National Academy of Sciences. The following were also elected members of the Council of the Academy for a three-year period: PROF. H. E. CARTER, head of the Department of Chemistry, University of Illinois; PROF. J. L. GREENSTEIN, head of the Department of Astrophysics and chairman of Faculty, Mount Wilson and Palomar Observatories, California Institute of Technology; PROF. W. O. FENN, professor of physiology, School of Medicine and Dentistry, University of Rochester; PROF. ESAU, emeritus professor of botany, University of California.

Zoological Society of London

THE Zoological Society of London has made the following awards: *Silver Medal*, Mr. D. Attenborough of Richmond, Surrey; *Scientific Medal*, Dr. E. H. Ashton, the Medical School, University of Birmingham; Mr. B. B. Boycott, University College, London; Dr. R. M. Laws, Nuffield Unit of Tropical Animal Ecology, Queen Elizabeth National Park, Uganda; *Stamford Raffles Award*, Dr. E. G. Neal, Taunton School, Somerset; *Thomas Henry Huxley Award*, Dr. J. S. Gray, University of Leeds; *Prince Philip Prize*, M. E. Greenhalgh, formerly of Kirkham Grammar School.

The Australian Academy of Science: New Officers

AT the annual election of officers of the Australian Academy of Science on April 28, the following were elected: *President*, Sir Macfarlane Burnet; *Secretary* (physical sciences), Dr. A. L. G. Rees; *Secretary* (biological sciences), Prof. R. J. Walsh; *Treasurer*, Sir Hugh Ennor.

New Fellows

ALSO at the annual general meeting of the Australian Academy of Science, LORD CASEY, the Governor-General, was elected a Fellow of the Academy by special election because of his service to the cause of science. The following were elected to fellowships by ordinary election: PROF. J. M. BLATT, professor of applied mathematics, University of New South Wales; DR. S. V. BOYDEN, professorial Fellow, Australian National University, Canberra; PROF. S. C. B. GASCOIGNE, assistant director, Mount Stromlo Observatory, Australian National University, Canberra; DR. S. D. HAMANN, chief of the Division of Physical Chemistry, C.S.I.R.O. Chemical Research Laboratories, Melbourne; PROF. A. E. RINGWOOD, Department of Geophysics, Australian National University, Canberra; PROF R. F. WHELAN, professor of physiology, University of Adelaide.

The Leopoldina German Academy of Sciences: Elections

THE Deutsche Akademie der Naturforscher Leopoldina, Halle, recently elected the following new members in the sections indicated: *Physics*, Prof. P. P. Ewald (New Milford), Prof. S. L. Mandelštam (Moscow) and Prof. E. Ruska (Berlin); *Meteorology*, Prof. H. Flohn (Bonn); *Chemistry*, Prof. G. Schwarzenbach (Zurich); *Mineralogy*, Prof. E. H. Jagodzinski (Munich); *Geology*, Prof. R. Hohl (Halle), Prof. H. Kölbel (Berlin), Prof. P. E. Kuenen (Groningen) and Prof. W. P. de Roever (Amsterdam); *Paediatrics*, Prof. J. H. P. Jonxis (Groningen); *Surgery*, Prof. K. Boshamer (Wuppertal-Barmen) and Prof. J. Kudász (Budapest); *Dermatology*, Prof. O. Braun-Falco (Marburg).

University News: London

PROF. J. R. D. FRANCIS, professor of municipal engineering in the Institute of Science and Technology, University of Manchester, has been appointed to the chair of hydraulics tenable at the Imperial College of Science and Technology.

Swansea

DR. R. H. TREDGOLD, reader in physics in the University College of North Wales, has been appointed to the chair of physics and headship of the Department of Physics in the University College of Swansea, on the resignation of Prof. F. Llewellyn-Jones, who has been appointed principal of the College.

Appointments

PROF. W. F. POUNDS has been appointed dean of the Alfred P. Sloan School of Management at the Massachusetts Institute of Technology as from April 1. Dr. Pounds is a specialist in operations management and quantitative managerial analysis, and has had extensive experience both in industry and in management education.

DR. L. COHEN has been appointed secretary to the Institute of Physics and the Physical Society. He has had wide experience in industrial research and has recently been research manager at Pyrotenax, Ltd. He has been honorary secretary of the Manchester Literary and Philosophical Society for 8 years.

Announcements

IN the Programme for 1965–66, Unesco, in co-operation with the International Brain Research Organization, is providing fellowships for research and training in the basic sciences concerned with the brain, together with funds to supplement offers of fellowships in brain research made by member States. Further information can be obtained from IBRO–UNESCO, 2 Place de Fontenoy, Paris 7*e*.

DR. N. D. ZINDER, professor of genetics and microbiology in the Rockefeller University, has received the United States Steel Foundation Award for distinguished work in molecular biology. Dr. Zinder and the group working with him were the first to show that virus replication in the RNA bacteriophage was not dependent on DNA; that, in fact, the RNA phage acts both as its own genetic material and as a template for directing protein synthesis.

IT has been agreed by the University of Reading and by the Fruit and Vegetable Preservation Research Association that the Research Association should become associated with the University. The Association, which is a non-profit-making company supported by the food industries, with grants from the Ministry of Technology, will not change its present constitution or objectives. The agreement will provide for certain lines of co-operation between the Association and appropriate University departments, such as those dealing with agriculture, and food science and technology.

THE forty-ninth annual conference of the Chemical Institute of Canada will be held in the University of Saskatchewan during June 6–8. Further information can be obtained from the Chemical Institute of Canada, 48 Rideau Street, Ottawa 2, Ontario.

THE 1966 San Diego Symposium for Biomedical Engineering on "From Diagnosis to Therapy" will be held in San Diego during June 6–9. Further information can be obtained from L. T. Gregg, 2063 Cardinal Drive, San Diego, California.

A SYMPOSIUM on "Energy Conversion by the Photosynthetic Apparatus' will be held at Brookhaven National Laboratory during June 6–9. Further information can be obtained from Dr. J. M. Olson, Biology Department, Brookhaven National Laboratory, Upton, New York.

A CONFERENCE on "Materials in Biomedical Engineering", sponsored by the New York Academy of Sciences, will be held in New York during June 9–11. Further information can be obtained from Dr. S. N. Levine, Department of Material Sciences, State University of New York, Stony Brook, Long Island, New York.

THE second international conference of the European Atomic Energy Agency on "Methods of Preparing and Storing Labelled Compounds" will be held in Brussels during June 6–11. Further information can be obtained from the Labelled Compounds Division, European Atomic Energy Agency, 51–53 Rue Belliard, Brussels.

A SERIES of summer courses in marine science will be held by the University of Texas Institute of Marine Science during June 3–August 6. The programme will include courses on marine microbiology, marine geology, ecology of fishes, marine chemistry, adaptive mechanisms in marine animals and estuarine ecology. Further information can be obtained from the Director, Institute of Marine Science, Port Aransas, Texas.

THE following summer courses will be held at the Enrico Fermi International School of Physics, Varenna: theory of magnetism in transition metals (June 6–25); interaction of high-energy particles with nuclei (June 27–July 9); plasma astrophysics (July 11–30). Further information can be obtained from Dr. G. G. Low, Atomic Energy Research Establishment, Harwell, near Didcot, Berkshire (course 1); Dr. T. E. O. Ericson, CERN, 1211 Geneva 23 (course 2); Dr. P. A. G. Scheuer, Cavendish Laboratory, Cambridge (course 3).

ERRATUM. The heading of the article entitled "Large Amounts of Deoxyphenylalanine in the Hydrolysate of Melanosomes from Harding-Passey Mouse Melanoma", by Dr. H. Takahashi and Prof. T. B. Fitzpatrick, which appeared on p. 888 of the February 26, 1966, issue of *Nature*, should read "Large Amounts of Dioxyphenylalanine . . .".

STABILITY OF EPIDEMIC PROCESSES

By WILLIAM GOFFMAN
Western Reserve University, Cleveland, Ohio

THE notion of stability of a physical process is closely associated with the theory of differential equations. In fact this problem has been studied extensively as a part of this theory, most notably by the Russian mathematician A. M. Lyapunov[1]. The methods of Lyapunov should thus be applicable in the investigation of any physical process which can be characterized in terms of a system of differential equations. It is the purpose of this article to show that the stability of an epidemic process is equivalent to stability in the sense of Lyapunov.

Epidemic Processes. In general an epidemic process E can be described in terms of a set N (a population) and a set of internal states σ (susceptible, infected and removed) which effects a partition of N at a given point in time, where state transitions are the result of exposure to some phenomenon (infectious material). The process E can itself be in any one of a set of three states at a point in time, namely: (1) Increasing state; the change in the rate at which the number of infectives accrues with respect to time is positive. (2) Decreasing state; the change in the rate at which the number of infectives accrues with respect to time is negative. (3) Stable state; the change in the rate at which the number of infectives accrues with respect to time is zero.

In its simplest form an epidemic process can be represented by the system (1) of differential equations[2].

$$\begin{aligned} \frac{dS}{dt} &= -\beta SI \\ \frac{dI}{dt} &= \beta SI - \gamma I \\ \frac{dR}{dt} &= \gamma I \end{aligned} \qquad (1)$$

This model assumes that there is a susceptible population of size S, an infective population of size I and a removed population R where removal constitutes an absorbing state which can be reached only by passing through a state of infection. It is further assumed that infection is spread by direct contact between susceptibles and infectives with β equal to the rate of infection and γ equal to the rate of removal. The total population $N = S + I + R$ remains constant with respect to time, there is homogeneous mixing among the members of N and the latency period equals the incubation period equals zero. That is, infections occur continuously in time and a susceptible becomes an infective as well as a manifest case at the time that effective contact occurs.

A necessary condition for the process of equations (1) to enter an increasing state is that

$$\frac{dI}{dt} = \beta SI - \gamma I > 0$$

Thus $S > \gamma/\beta = \rho$ constitutes a threshold density of susceptibles, that is, an epidemic can develop from time t_0 only if the number of susceptibles S_0 at that time exceeds the threshold ρ.

The process will attain a peak at the point in time at which the rate of change of susceptibles and infectives is maximum, that is, when:

$$\frac{d^2(S+I)}{dt^2} = -\gamma \frac{dI}{dt} = -\gamma[\beta SI - \gamma I] = 0$$

and $S = \frac{\gamma}{\beta} = \rho$. Therefore the point at which the process will make a transition from an increasing to a decreasing state is that point in time when the number of susceptibles reaches the threshold ρ.

According to the Kermack–McKendrick theorem[3] for processes of type (1), the initial number of susceptibles will be reduced over the course of the epidemic by a value as far below the threshold as it was originally above it. Hence if:

$$S_0 = \rho + \varepsilon$$

then the point at which the process re-enters a stable state is the point at which:

$$S = \rho - \varepsilon$$

Since N remains constant throughout the course of development of the process, that is, N is a closed population, the process of equations (1) must always return to a stable state after having entered an increasing state. This is, in fact, one of the principles underlying the effectiveness of quarantine as a control. Thus an epidemic process in a closed population is in a sense a stable process.

Let us now consider an epidemic process in an open population, that is, in a population N which does not remain constant with time. In such a process new supplies of susceptibles and infectives are introduced into the population as the process proceeds on its course of development. We again consider a population N consisting of S susceptibles, I infectives and R removals in which infectious material is transmitted by direct contact between members of I and members of S. β is the rate of infection, $\delta(\gamma)$ the rate of removal of susceptibles (infectives) and $\mu(\nu)$ is the rate at which new susceptibles (infectives) are introduced in N. If the assumptions concerning mixing, latency and incubation are the same as before, this process can be represented by the system of equations (2):

$$\begin{aligned} \frac{dS}{dt} &= -\beta SI - \delta S + u \\ \frac{dI}{dt} &= \beta SI - \gamma I + \nu \\ \frac{dR}{dt} &= \delta S + \gamma I \end{aligned} \qquad (2)$$

A threshold density of susceptibles is obtained as before. Thus, if a single infective is introduced into a population of S_0 susceptibles at time t_0, then:

$$S_0 > \frac{\gamma - \nu}{\beta} = \rho$$

is a necessary condition for the process in equations (2) to enter an increasing state, that is, for an epidemic to develop. Since N is open, that is, increasing with time, there is no guarantee that if the process (2) enters an increasing state that it will reach a maximum, make a transition to a decreasing state and subsequently to a stable state as is the case when N is closed. Necessary and sufficient conditions for a process of type (2) to stabilize itself have been given[4]. It was shown that such a process will be stable if and only if $dR/dt = \delta S + \gamma I$ is constant.

Stability. Consider a physical process which can be described by a system of differential equations of the form:

$$\frac{dx_i}{dt} = f_i(x_1, x_2, \ldots x_n) \quad i = 1,2, \ldots n \qquad (3)$$

where the x_i's represent the variables which characterize the process. These variables are called the phase coordinates of the process and are usually functions of time t. Since the behaviour of equations (3) is described by the values of the n real numbers $x_1, x_2, \ldots x_n$, that is, by the

vector $\bar{x} = (x_1, x_2, \ldots x_n)$, the vector space X of vectors $\bar{x}$ constitutes a phase space for the system (3). Thus equation (3) can be written in vector form:

$$\frac{d\bar{x}}{dt} = f(\bar{x}) \quad \bar{x} = (x_1, x_2, \ldots x_n) \tag{4}$$

A system of differential equations always has an infinite number of solutions. A definite solution is obtained by specifying a set of initial values which correspond to the initial conditions of the process that the equations are intended to describe. By the uniqueness theorem[5] a solution or trajectory passing through a given point is unique. Suppose that the phase co-ordinates of equation (4) have reached a fixed point $\bar{a} = (a_1, a_2, \ldots, a_n)$. Then $f(\bar{a}) = 0$ and $\bar{x} = \bar{a}$ represents a state of equilibrium for the process characterized by (4). The problem of stability is concerned with how trajectories g^* which pass near a point of equilibrium $\bar{a}$ behave with respect to the trajectory g passing through $\bar{a}$. If the g^* remain close to g then the point $\bar{a}$ is said to be stable.

It is convenient to consider $\bar{a}$ as the initial point of the process, and hence as the origin of the phase space X. This is easily accomplished geometrically by the transformation of co-ordinates so that we shall be dealing with a system of equations for which $f(0) = 0$. The question of stability can now be stated in terms of the origin of the process. Thus the origin $\bar{a}$ is said to be stable in the sense of Lyapunov if there exists an n-dimensional spherical region $S(H)$ of radius H surrounding $\bar{a}$ such that for $h \leqq H$ a trajectory g^* emanating from a point $\bar{x}_0$ in the interior of the region $S(h)$ of radius h will remain within the region $S(H)$. In other words, if the trajectory g starting from $\bar{a}$ is thought of as being encased by a tubing then a trajectory starting near $\bar{a}$ which penetrates this tubing must remain within a larger encasement of tubing. On the other hand, the origin is said to be unstable if for any h, no matter how small, a trajectory emanating from the interior of $S(h)$ reaches the border of $S(H)$.

The method of Lyapunov[6] reduces these considerations to the properties of a special type of function V. A function $V(x_i)$ is called a Lyapunov function if (1) $V(x_i)$ together with its first partial derivatives are continuous in a certain region Ω about the origin, (2) $V(0) = 0$, (3) $V(x_i)$ is positive everywhere except at the origin, (4) $\frac{dV}{dt} \leqq 0$. Lyapunov's stability theorem states that the origin is stable if there exists a Lyapunov function in some neighbourhood of the origin. That is, a disturbed motion near the origin is stable in the sense of Lyapunov if it is possible to find a function which is sign-definite and whose derivative is either sign-opposite to it or vanishes immediately.

The epidemic process of type (2) can be represented by a system of equations of the form:

$$\begin{aligned} \frac{dS}{dt} &= f_1(S, I, R) \\ \frac{dI}{dt} &= f_2(S, I, R) \\ \frac{dR}{dt} &= f_3(S, I, R) \end{aligned} \tag{5}$$

where f_1, f_2 and f_3 are single-valued functions, continuous in the domain of their arguments S, I, R which are unknown functions of the real variable t. The system of equations (5) can be treated as a 3-dimensional vector space E which constitutes a phase space with phase co-ordinates S, I and R for the epidemic process. It was shown that a process of type (2) will be stable if and only if $\frac{dR}{dt} = k$ where k is a constant. It can be seen that if this is the case then $\frac{dR}{dt} = V(S, I)$ possesses the properties required of a Lyapunov function, hence its existence in the neighbourhood of the origin guarantees its stability. For let $\bar{a} = (S_0, 1, 0)$ be the initial state of the process. By translation of co-ordinates, $\bar{a}$ can be taken as the origin of the phase space E. Clearly (*a*) $V(S, I)$ together with its first partial derivatives are continuous in the neighbourhood of the origin; (*b*) $V(0) = 0$; (*c*) $V(S, I)$ is positive everywhere except at the origin; (*d*) $\frac{dV}{dt} = 0$ since $\frac{dR}{dt} = k$.

Since $V(S, I)$ is positive everywhere except at the origin, the surface $y = V(S, I)$ has the general shape of a cup emanating from the origin and $V(S, I) = k$ represents loops around the origin for different values of k.

Given a spherical region $S(H)$ surrounding the origin, there exists a loop K_H, determined by some k_H which lies just within the sphere $S(H)$. There also exists an $h \leqq H$ such that the sphere $S(h)$ lies just within the loop K_H. Consider a point $\bar{x}_0$ in the interior of $S(h)$ and a trajectory g^* starting at $\bar{x}_0$. Since $V(S, I) < k_H$ at the point $\bar{x}_0$ and since V is non-increasing, it follows that g^* will never reach the loop K_H. Hence g^* will always remain within $S(H)$. Thus any trajectory emanating from the region $S(h)$ surrounding the origin will remain within the region $S(H)$, hence the origin is stable.

PROBLEMS OF HEAT TRANSFER IN LAKE VANDA, A DENSITY STRATIFIED ANTARCTIC LAKE

By R. A. HOARE

Victoria University of Wellington, New Zealand

LAKE Vanda (77° 35′ S., 161° 39′ E.) is a permanently ice-covered lake which occupies a depression in the Wright Valley, Victoria Land, Antarctica. It is about 5 miles long and 1 mile wide, is fed by melt-water from glaciers, has no outlet, and all water loss is by evaporation. It is of unusual interest because of its relatively high bottom temperature of 25° C in a region the mean annual air temperature of which is about −20° C, and its strong density stratification caused by a salt concentration which increases with depth from zero at the top up to 10 per cent by weight at the bottom. Several expeditions have measured temperatures in the lake[1–4] and established that the isothermal surfaces are horizontal, over most of the area of the lake, and that the temperature increases downwards, reaching a maximum of 25° C at the bottom. The decrease in density to be expected from the increase in temperature is more than compensated by the increasing salt content.

Wilson and Wellman[3] showed that the shape of the temperature profile below 160 ft. is consistent with the supply of heat to the water by the absorption of solar radiation, with conduction as the only other form of heat transfer, and that the necessary amount of energy is capable of penetrating the surface ice and water to this depth. They found that from 160 ft. to 125 ft. the temperature gradient is much less than that below 160 ft., so that much less heat can be conducted upwards above the 160 ft. level than below it. This implies that either the temperature at the 160-ft. level is rapidly increasing with time, or the heat transfer above this level is not solely by conduction. As the density appeared to increase downwards, it seemed unlikely that convection could be responsible; this article reports the investigations which I undertook to resolve the problem.

Wilson and Wellman reported that there were no changes in temperature, density or concentration from 125 ft. to 55 ft., which is consistent with strong convection in this region; however, they considered the region from 55 ft. up to 20 ft. to be another anomalous region. Ragotzkie and Likens[4] obtained temperature measurements similar to those of Wilson and Wellman and showed by radioactive tracer methods that convection occurred in the region from 45 ft. to 70 ft. They postulated a set of four convection cells extending over most of the area of the lake, and ranging in thickness from 5 ft. to 65 ft. The present article provides additional evidence for solar heating, and shows that the anomalous regions consist of a series of conductive and convective layers.

In early January 1964 I undertook detailed *in situ* measurements of temperature, density and electrical conductivity of the lake waters. Temperature was measured to $\pm 0{\cdot}05°$ C at all depths using a copper-constantan thermocouple with a portable potentiometer, and to $\pm 0{\cdot}01°$ C to a depth of 65 ft. using a multiple thermocouple which consisted of six thermocouples in series.

Density was measured by weighing a 'Perspex' cylinder of volume 568 c.c. suspended on light nylon monofilament line, which was wound on a reel hooked on to the balance arm. A simple balance with an accuracy of about ± 10 mg was used, mounted in its case directly over a hole in the ice. Changes in the density of the water displaced at different depths resulted in changes in the 'apparent' weight of the 'Perspex' cylinder. A correction was made for the change in apparent weight of the suspending line when it was run off the reel into the water. The main sources of error result from changes in the volume of the 'Perspex' cylinder due to changes in temperature and pressure. The effect due to pressure is negligible at the present degree of accuracy, and that due to temperature is found to be sufficiently small that general conclusions will not be altered. (There was a small apparent difference in density of the top water between two measurements, one taken at the start of a run, and the other after pulling the 'Perspex' cylinder up quickly from the warm bottom waters). The 'Perspex' cylinder was 8 in. (22 cm) long, so that detailed structure of density was not clear.

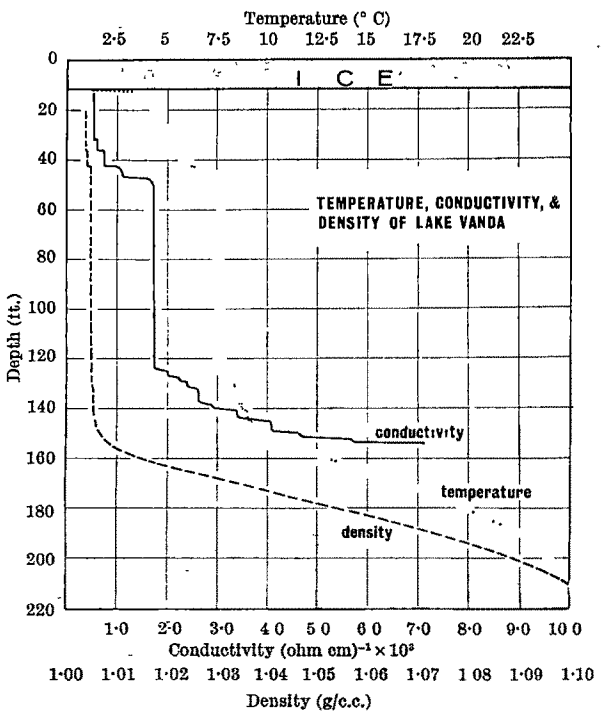

Fig. 1

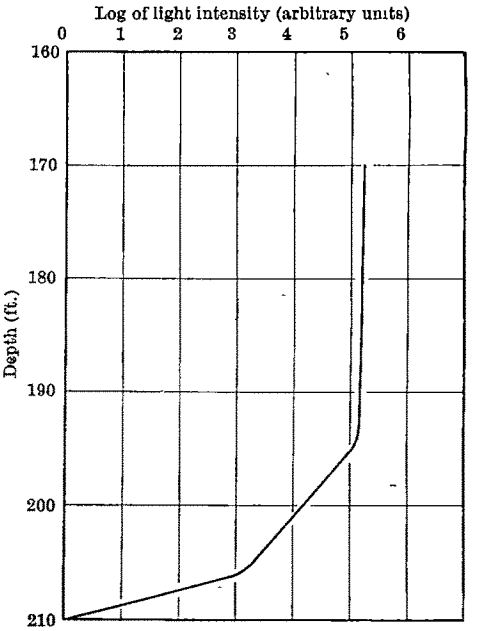

Fig. 2

Electrical conductivity was measured to a depth of 155 ft. with a Whitney underwater conductance meter (Whitney Underwater Instruments, Ltd., San Luis Obispo, California).

Measurements were taken at intervals which depended on the rate of change of the quantity being measured, and were sometimes as close as 3 in. ($7\frac{1}{2}$ cm). Temperature measurements were made in two holes, about a mile (1·6 km) apart, while the other measurements were made in only one of these. Depths were measured with respect to water-level, which was 9·0 ft. below a bench mark established by my expedition near the middle of the south side of the lake (the bench mark consists of a cairn of rocks, with a reference line and the January 1964 height above water-level painted on it).

Heat transfer below 160 *ft.* Fig. 1 shows the temperature profile which I observed in early January 1964 through the second hole, at a position near Wilson and Wellman's second hole, and about 400 m south-west of Ragotzkie and Likens's 2,000-m station. The profile has the same shape as that reported by Wilson and Wellman, between 160 ft. and 200 ft., but about 0·5° C higher, so that, for the reasons given by them, heat transfer is by conduction and radiation. (Both sets of measurements were performed with the same copper constantan thermocouple and with respect to an ice-water cold junction.) At the 200-ft. level the temperature gradient decreases more abruptly than that reported by Wilson and Wellman, in a similar manner to Ragotzkie and Likens's results for late December 1962. The temperature gradient increases again at 205 ft., which is inconsistent with steady-state heat transfer by

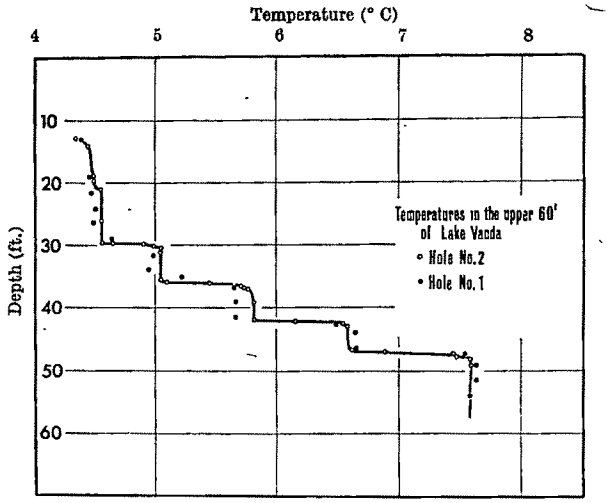

Fig. 3

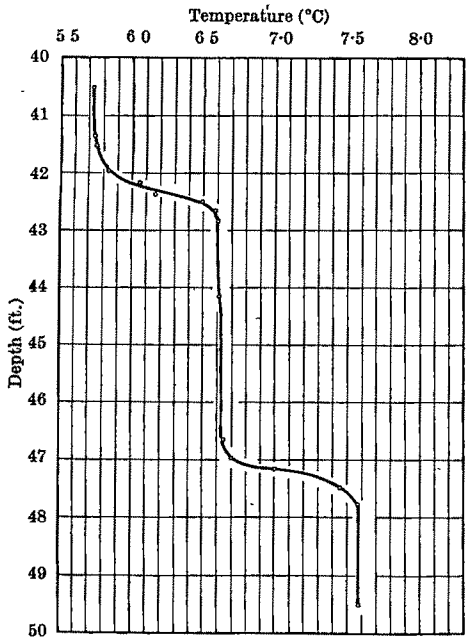

Fig. 4

conduction alone. This region of the lake has a high optical density (extinction coefficient), as shown by measurements of light intensity made with a selenium photo-electric cell and potentiometer (see Fig. 2). The difference between Wilson and Wellman's measurements and subsequent ones may indicate that their bottom coring operations disturbed the lake bottom and resulted in the discoloration of the water (personal communication), and that the present temperatures are not steady-state temperatures because of consequent alterations in the radiated heat.

Heat transfer above 160 *ft.* The electrical conductivity measurements through the second hole are shown in Fig. 1 to a depth of 155 ft., below which the concentration was too high to allow reliable correction for polarization. Hole 1 was about a mile (1·6 km) to the east of the hole 2, and the temperatures in the upper region of the lake at the two holes are compared in Fig. 3. It can be seen that the temperatures, although slightly different at the two holes, change at the same depths at both holes.

These regions of constant temperature and conductivity can only be explained by supposing that they are strongly convecting. The foregoing measurements show that the reason for the anomalously low value for the average temperature gradient in the region between the top and 160 ft. is that twelve convecting regions transfer heat upwards with a very small temperature gradient, the boundaries between these regions being horizontal and extending across the whole lake. Within each convecting region the temperature, salinity and density are constant—within the limit of accuracy of these measurements. At the boundaries of these regions temperature and salinity rise smoothly, as in the lower, density stratified region. This is illustrated by the results shown in Fig. 4, which are temperatures taken between 40 ft. and 50 ft. with the multiple junction thermocouple.

If the boundary regions are assumed to be non-convective, it is possible to calculate the heat flow through them and compare it with that expected on the basis of solar heating.

The two boundaries shown have maximum temperature gradients of about 1·3 ± 0·2° C/ft. At a depth of 160 ft., the gradient is 0·4° C/ft., so if the thermal conductivity of the water at 50 ft. is the same as that at 160 ft., about four and a half times as much heat is conducting upwards at the higher level than at the lower one.

I was able to detect, by means of a thermopile-type bolometer, that solar radiation halved in intensity every 50 ft. This means that a quarter of the light reaching 50 ft. will reach 150 ft. If the heat flowing upwards is derived from solar radiation which is being absorbed in the water, then the heat flow would be expected to be four times greater at 50 ft. than at 150 ft.—which is in agreement with the foregoing measurements of temperature gradient.

The observed temperatures agree well with the theory that the heat in the lake comes from absorbed solar radiation. In the lower waters of Lake Vanda heat transfer upwards is by conduction through the density stratified water. Above this region, convecting layers ranging in thickness from a few feet to 70 ft. alternate with conducting layers a few inches thick. The limited data available (see also ref. 4) indicate that the boundaries are horizontal and extend across the entire lake.

These convecting layers are among the most stable, large, natural convective systems in the world. The ice cover of the lake provides a stable platform from which instruments can be lowered to any point within the convective cells.

Apart from their interest to studies of convective systems in general, there is the challenging problem of the origin of the convecting regions. One possible mechanism is that at some time the lake was continuously, but weakly, density stratified. The heat conducted upwards would have produced temperatures which increased with depth, which would have caused the density to decrease with depth by thermal expansion. If the heat flow were sufficiently high, the thermal expansion might have overcome the salt-produced density stratification, and enabled convection to commence. The vertical dimension of the convection cell would have been limited by the gradients of salt concentration and temperature, and would have depended on the variation of thermal expansion of water with temperature and salt content. Further work is in progress to elucidate details of this problem.
